Sorry for the double posting, but I just thought of an experiment
that will settle everything.

Take W8JI's 100 uH coil. Keep the spacing between coil 1 and
coil 100 the same at one foot. Get rid of all the other coils
leaving only coil 1 and coil 100 separated by one foot of air.
Use coil 1 as the primary coil and measure the coupling from
coil 1 to coil 100. If it is 100%, you will have made believers
out of everyone and we can stop this silly argument.

The lumped circuit theory says that all the flux in coil 1
links to coil 100 one foot away just as if they were
both tightly wrapped around a toroid.

So there's the challenge. Simply prove that 2" dia coils one
foot apart in air transfer all the energy from one coil to
the other. Piece of cake.

Maybe it is - within ï¿½59% (after fudging the Vf)

Cecil's theories allows for so many possibilities ;-)

Yes, that's why inductive loading is more efficient than
linear loading. The inductor has the advantage of adjacent
wire flux coupling. However, the farther away in space that
a particular coil is located from a reference coil, the lower
the coupling. I just issued a challenge to anyone to prove that
the coupling between 2" dia coils separated by one foot of
air is 100%. If anyone can do that, I will admit I am wrong.

I would have loved to have invented the distributed network
model, but it was proven valid and in widespread use long
before I was born. But apparently, it has been forgotten
in the past half-century. The results are otherwise intelligent
engineers trying to use an unchanging standing wave phase to
measure the phase shift through a loading coil in a standing wave
antenna system, not realizing that the phase of the standing wave
current cannot even be used to measure the phase shift in
a piece of wire (since it is virtually unchanging).

Thanks Reg, but I'm sure most people already understand that. I think those who have been following this thread and who don't understand that are beyond help.

As a matter of fact if we all just go back to the very first post you made, we'll see nothing has changed from what you initially said.

I'm sure the 800-post thread will continue another 800 posts. People must be bored.

Actually, they are wondering how you are going to prove 100%
coupling between coil 1 and coil 100 in your 100uH coil such
that the result was 3 nS of delay over that one foot length.

I've got a Butternut vertical HF6V and have plans to place it up on the roof. I've had it ground mounted (worked super) but due to family uses for the yard will have to move it up and out of the way.

Rather than laying down 20 pieces of wire on my roof for radials (insulated with the tips protected) I'd like to try and build a Butternut "No radials required with the optional CPK Counterpoise kit" but I'm having difficulty finding the specs.

Has anyone ever built one or have the measurements for a general purpose counterpoise kit?

Thanks.

John

Just run the radials... it will take around 550ft of wire.... I have my 5BTV
on the roof with 20 radials... the 75 meter radials are guyed out to trees.
It works very much good. :-)

Cecil, W5DXP wrote:
"Actually, they are wondering how you are going to prove 100% coupling between coil #1 and #100 in your 100 uH coil such that the result was 1 nS delay over that one foot length."

Yes. I think turn-to-turn capacitance doesn`t amount to much and won`t bypass the coil as you have 100 small capacitors in series, so their sum approaches zero.

The speed of the wave is almost 984 feet per microsecond. At 75 meters (4 MHz), 1/4-wave is about 60 feet, and this corresponds to 90-degrees. The delay corresponding to the time required to establish current in the coil to induce voltage seems trivial to me. Almost instantaneous transmission between the first and last coil turns should be possible were they tightly coupled.

But, I think Cecil is on to something. I`ve played with antique radios using front panel adjustment to control distance between two coils on the same axis to control their mutual impedance. You only had a couple inches of adjustment which was enough to seriously decouple the coils. 12-inch separation would surely have almost completely decoupled them. This much separation was not available as I`m sure it is unnecessary.

Best regards, Richard Harrison, KB5WZI

Oops, wait a minute. Just a couple of hours ago you said the current would have to wind its way around each turn, following the wire from one end to the other, and that it would take nearly the wire length divided by the speed of light. Have you changed your mind about how inductors work?

It's not a straw man if someone actually believes it. We
have a 2" dia. x 12" long coil. That's a length to diameter
ratio of 6/1. There's no way coil 1 links all its flux to
coil 100. Yet the *measured* delay through that coil was
3 nS. EZNEC says the delay through a better linked 70 uH
coil is 6.22 nS.

Have you noticed that the coils having instantaneous
propagation times have been getting smaller and smaller
and more conceptual rather than real?

Oh, there's a certain element of fun in "seeing what works." Try to find a ham who's never tried
anything goofy -- it can't be done!

At that frequency, you can do a great deal with a cone of metal mesh (a minor purchase at the
hardware store). Put the small end around the antenna and the open end pointed in the direction
of the desired signal.

My entry into that band was not ham or Wi-Fi, but MDS television. There is a TV band around 2300 MHz. (I don't really want to go out in my cold garage and look
it up.)

I bought a downconverter for that band (which was used for porno movies in my area at the time) but I didn't have enough signal. So, I started goofing with mesh cones.
I got big time improvement with very little effort.

If the aim is just experimentation, then a three-foot metal mesh cone will actually be an appealing
feature of the setup.

Cecil sure is selective in presenting data.

He alters dimensions and anything else that gets in his way. He dismisses EZNEC when it disagrees with him (he did that just a dozen or two posts ago), he uses it when it suits him.

What a character!

It's a simplification of any real-life coil - but loading by
pure-and-simple lumped inductance is also a vital test case.

This form of loading is the simplest imaginable. If a theory about the
behaviour of loaded antennas fails to give correct results for this very
simplest test case, it cannot be valid... and all the further
elaborations about real-life coils will not be valid either.

Cecil's theory does work for this test case, because it requires that
basic electrical properties like current and inductance switch into a
different kind of behaviour in what he calls a "standing wave
environment". But it is an absolutely basic fact that the physical world
does NOT change its behaviour according to the way we choose to think
about it. If any theory requires that, it's an absolute proof that such
theory is false.

For the avoidance of doubt (as they say in Scottish legal documents):
It certainly IS possible to analyse and predict the behaviour of
coil-loaded antennas in terms of travelling and standing waves. My
objection is specifically against Cecil's method, which is provably
incorrect.

(Away now to the GMDX Convention, so no replies till Monday.)

I don't remember the exact dimensions of your coil so you might refresh my memory. Was it 100 turns at 8 TPI? I have the same coil stock in a 50 uH version.

As far as the EZNEC files go, I created them. Gene altered they away from the agreed upon length specifications. I altered them back and corrected a mistake I made in the traveling wave configuration.

It only tests the validity of the lumped-circuit model. It does
NOT test the validity of the real world. Testing the validity
of the real world is best left to metaphysicians, not engineers.

Whoa there, Ian. You are confusing cause and effect. If the lumped
inductance fails to give correct real-world results, then it must
be abandoned in favor of a more powerful model, e.g. the distributed
network model.

You are making my argument for me. Do you really believe a 2" dia
x 12 inch coil has 100% flux linkage between coil 1 and coil 100?

> But it is an absolutely basic fact that the physical world
> does NOT change its behaviour according to the way we choose to think
> about it.

Exactly! Choosing to think about an inductance as "lumped" does
NOT change the behavior of the coil. The behavior of the coil
is what it is. Choosing to think about it as "lumped" is often
an over-simplification, a fantasy existing only in someone's mind.

The distributed network model, a superset of the lumped circuit
model, is "provably incorrect" after being accepted and tested
for more than a century??? By all means, please prove it incorrect.
That should be very interesting - overturning a century of
acceptance.

Ian,

It seems to me Cecil now agrees the system can be modeled as a lumped components and loads and we do not need to use standing waves.

At least that's what it sounds to me like what he is saying now.

Reg -

You removed the important part of your post. I will quote it. You said:

"The presence of ferrite has hardly any effect."

This is what I do not understand. If the ferrite has hardly any effect, then explain to me why plastic could not be used as long as the plastic torus is shaped the same.

Now you say it wouldn't be a choke. Why not? As long as the shape of the turns of wire are the same without the ferrite, why would it not be a choke without the ferrite which has "hardly any effect"?

I am not trying to pick an argument. I am trying to understand something that goes against everything I have been taught.

Thanks,
John

But, you said, "The presence of ferrite has hardly any effect." Why are you bringing up ferrite again? Why is ferrite used if it has hardly any effect? Is there not a cheaper material?

Cecil,

That's quite remarkable.

You issued a "challenge" to design and report on a loading coil for 4 MHz, with a whip of 8 feet. I responded with a solution that used a whip length of 10 feet. I did not "alter" anything, and I told you exactly what I did.

What came back in return?

Three separate times you altered my file and reported back here that something was incorrectly designed, illegal, or just plain different. You did not acknowledge the changes you made until I complained. (EZNEC did not change the coil pitch or connect the bottom of the coil to the top of the coil.)

I don't have a copy of the IEEE Dictionary, but I believe the correct descriptive word for your action is dishonesty.

Depends on how bad a mismatch and how much RF you're
going to cram through it. For easier setups, like a dipole and
100w, A LDG Z100 will work. Need more? Get an LDG AT200Pro
or 100 pro. If you are QRP, try a Z11, also from LDG.

I've had experience with all the above tuners (except the 200 which
UPS left on my porch then got stolen.) Anyways, LDG makes
a fair to excellent product line HOWEVER, My K2's internal tuner
will tune a worse match than any of the listed LDG tuners. Of course
if you want a KAT2 tuner, You'll need a K2 to install it in....

I know - you were just looking for an excuse to build a K2, right?

Recently heard about EH antennas and have done some research into them including reading some articles in this newsgroup. It is begining ti sound very much like my friends homemade FM/TV antenna. My friend being short on money fastened an old bicycle rim to a piece of galvanized pipe(axel stuck in the pipe) Feedline was connected from the center o the wheel to a point on the outer rim. I had repeated told my friend that something like this would never work and he demonstrated to me that it did.. I theink the EH antenna is a lot like this old wheel, just about anything placed on a mast with work to some degree. In this case a very poor antenna allowed my friend to receive 2 TV stations and 4 or 5 FM radio stations. This was a vast improvement over the 0 tv and Fm stations he was receving before putting up his "antenna" Would it be appropriate to say that an EH antenna is more like a coupler that utilises the antenna support structure(tower/mast) and feedline as the radiating elements of the antenna?.

Roy, W7EL wrote:
"Just a couple of hours ago you said the current would have to wind its way atound each turn, following the wire from one end to the other, and it would take nearly the wire length divided by the speed of light."

Yes, and I`m still convinced that is the case in an air cored r-f coil that is long because the coupling between ends of the coil isn`t enough to bypass the delay of the coil.

I posted speculations on bypassing the delay in the coil. Capacitance between turns is too small over the length of the coil, said to be about one loot, and about 100 turns.

Tom, W8JI had said that magnetic coupling between the start and finish of the coil bypassed the time delay of following the path of the wire. Well, nothing happens instantly when voltage is applied across a coil. 90-degrees after the voltage has crossed the zero axis on its way up, the current does the same. It lags the voltage by 90-degrees. It`s the current which induces a voltage in the coil and this is delayed by the forces predicted by Lenz`s law. 90-degrees at 4 MHz equates to about the time required for a radio wave to traverse about 60 feet of thin wire.

100 turns of wire on a 2-inch form requires about 52 feet of wire. The current travels from start to finish on the coil before the current reaches its maximum in the coil and before energy could be effectively induced from one end of the coil to the other. The wave velocity is about 984 feet per microsecond.

These are just musings aloud and confirm my speculation that signal progress is through conduction on the surface of the wire of the coil.

Best regards, Richard Harrison, KB5WZI

Hi Richard,

This "approaches zero" capacitance for a coil has been tossed out so many times it is approaching infinity.

For the commonplace coils in these applications, we have rather non-trivial self capacitances. Why, when this evaluates to on the order of 10-12 pF, that so many feel it incumbent to dismiss mutual capacitances, then it does not follow.

Yuri's 60 turn coil may have 60 series capacitors, but it also has 60 parallel capacitances too. A back-of-the-napkin calculation for one turn-to-turn capacitance finds
23.3pF
If we look at the capacitance between the first and last
0.2pF

The capacitance seen at the first loop, then, is a combination of series/parallel capacitances to all other windings that, on average, approaches a dozen picofarads.

The apparent capacitance based on reported resonances and modeled reactance is on the order 12-14pF.

So, across the board and considering that this is RF, and HF at that, the dismissal of capacitances are unwarranted.

Hi John,

No, you are no more dense than the next, and Reggie's bafflegab is no
more distinct than all that which preceded it - once you discard his
pretension.

If you simply want an explanation from him, we can all see how much
desire will be filled from that. On the other hand, there may soon be
an unzipped executable released soon.

If you simply want to know why he uttered
>> John, yes you would. But you would not have the choke.

The ferrite is wholly transparent to the differential currents (the
balanced and thus equally opposing line currents). Its presence or
absences is immaterial. This is the abstraction of Reggie's bafflegab
for instead simply saying you don't need a choke (the lines' balance
proves that).

Now, if that condition of balance were to ever go away (like we leave
that comfortable illusion and return to reality), then the absence of
the ferrite has also rendered your "choke" chokeless (by the degree of
its contribution because in spite of Reggie's claim, the turns of your
coil remains a choke, if only an inadequate one).

Cecil wrote, AMONG OTHER THINGS,

"If 100% of the flux from each and every coil physically linked
100% of each and every other coil, the current would indeed skip
from one end of the coil to the other without interference. That
is the basic presupposition of the lumped-circuit model. "

There is so much wrong with all that, that I hardly even know where to
begin.

First, with k=1 coefficient of coupling among a series string of
self-inductances, you STILL get transmission line behaviour, with
practically the same delay for the same net inductance and same shunt
capacitance as if you model them as independent inductances. So just
because you have complete flux linkage between two coils, you do NOT
necessarily have instantaneous, or even speed-of-light, propagation of
signal from one to another, if you've correctly considered everything.

Because of that, it is crystal-clear that that is NOT "the basic
presupposition of the lumped-circuit model."

If you cut components out of a model, you should NOT expect the model
to behave as it did before. If you cut out 98 percent of a coil (with
its inductance, capacitances, resistance--all of which are frequency
dependent to some degree), OF COURSE you are not going to get the same
answer, and more importantly, the answer you get may bear no
resemblance to the actual performance of the system you were trying to
get some insight into.

impedance mactching is a manifestation of reflections from source to load then load to source.as we know,the propagation of this signal is dependent on the dialectric of the propagation channel.
what is the critical length as to when to consider it as a long or short?
or when do we need to at least go away with trace-length impedance matching to buy some space in a fr4 board in 2.4ghz systems?

Heck, Cecil, I don't see Ian saying that a proper distributed model is incorrect at all. I see him saying that YOUR model is incorrect! -- For the record, YOU and YOUR below translate to Cecil and Cecil's.

YOUR model doesn't have any capacitance to the outside world, as YOU have posted and repeated till you are perhaps blue in the face. (No charge storage translates very directly to no capacitance, in case anyone could have missed that.)

Because of that YOUR model has, guess what, ZERO time delay along the coil.

It is ONLY through a combination of both inductance AND capacitance that you get propagation velocities equal to or less than the speed of light.

NOTE that in freespace, the speed of light, c, is exactly equal to 1/sqrt(epsilon_naught * mu_naught) -- and the units of epsilon_naught (freespace permittivity) are FARADS per meter, and mu_naught (freespace permeability) are HENRIES per meter. A coil increases the henries per meter, but somehow we seem to have gotten in YOUR model to some space around the coil in which the permittivity is _zero_ so that we don't have any capacitance in YOUR model. That would be a good trick, but it's not one that Ian and I are buying. I suppose that W8JI and Tom D and Roy and Wes and Reg and Gene and John P and probably the two Richards and some others are ALSO not buying. Why, even the detailed Tesla coil calculations I've seen consider the distributed capacitance to the outside world, in great detail. I'd bet that the authors of those calculations would ALSO not buy your model.

Putting it another way, propagation of an EM wave requires an interchange of energy between electric and magnetic fields. With zero permittivity, there would be no energy stored in the electric field, and no EM wave. (In a TEM transmission line, it's often said that the energy is stored in capacitance and inductance along the line, but that's no different than saying the energy is stored in electric and magnetic fields.)

It amazes me that you fought so hard for a distributed model in which that capacitance to the outside world is missing, but insist that the resulting model allows a non-zero time delay. That's YOUR model; it's all in the stuff YOU have posted for anyone that wants to go look at it. By denying the capacitance in the model, YOU are the one who doesn't accept what's been know since Maxwell and Faraday and Tesla and...

But YOUR model isn't any use to me, and it seems that it's no use to Ian. We'd prefer a model that actually accounts for all the currents correctly, and actually allows for a delay along a transmission-line structure. Then, knowing it's an ACCURATE model when we can verify through specific measurements that it agrees to an acceptable level with those cases we measured, we can look at ways to use that model as-is, or to use a model which makes life easier for us which matches the very accurate one closely enough for our purposes.

(Not only does YOUR model with no capacitance to the outside world have zero propagation delay, but it ALSO leads to a line with infinite impedance, which I'm ALSO not buying, though with zero delay, the line impedance really doesn't matter. Also notice that with no capacitance to the outside world in that area, the model collapses to exactly the one YOU are arguing AGAINST, except that the straight sections of antenna are apparently not in the zero-permittivity area, so we need to keep them separated...it leads to a very strange model, indeed!)

And please note that in the paragraphs above, the only models specifically mentioned are DISTRIBUTED ones, so don't go giving me any bullshit about the other kind. And you can save any bullshit about accepting the fact of capacitance to the outside world, because your postings repeatedly say otherwise.

w8ji@akorn.net wrote:
> It seems to me Cecil now agrees the system can be modeled as a lumped
> components and loads and we do not need to use standing waves.

A 100% false statement but we are accustomed to such from
W8JI. Since the lumped circuit model is a subset of the
distributed network model, if there is any disagreement
between the two models, the distributed network model wins
every time. They are both right under certain conditions
and the lumped circuit model is wrong under certain
conditions.

Quoting from: http://www.ttr.com/corum/index.htm

"There are no standing waves [allowed] on a lumped element
circuit component. ... for coils whose WIRE LENGTH exceeds
1/6WL", the distributed network model is required.

Quoting from: http://www.ttr.com/TELSIKS2001-MASTER-1.pdf

Concerning the *impedance only* of a loading coil:

"The formula will NOT (and, being lumped, can not) give the
voltage magnification by VSWR dur to physically true
current standing waves on the structure ... If impedance is
the only item of interest, the empirical Medhurst approximation
is acceptable out to about 60 degrees."

But we haven't been arguing about impedance. We have been
arguing about phase. Here's what the above paper says about
phase shift through a loading coil.

"Further, the voltage distribution passes from the loop of a
sinusoid (at 90 degrees) to the linear portion of the sinusoid
(for heights less than 15 degrees)."

It is necessary to use the distributed network model if the
phase shift through the coil is greater than 15 degrees.

Continuing the quote: "Lumped elements 'have no physical
dimensions and no preferred orientation in space; they
can be moved around and rotated at will.' Not so for real
world coils. ... The concept of coil 'self capacitance' is
an attempt to circumvent transmission line effects on small
coils when the current distributions begins to depart from
its DC behavior."

Clearly it's not black-and-white. Whatever trace you have will have SOME impedance as a transmission line, and if that impedance is close enough to what you want, it's going to work OK. As a rule of thumb, I'd say that any trace over 1/10th of a wavelength long, considering the propagation velocity of the medium, deserves consideration as a transmission line. In critical applications, I've considered traces as short about 1/200 of a wavelength to be transmission lines, but that was more because it was just as easy to do that with the tools I use, as to figure the inductance and capacitance and use them.

Also, if you are working in a 50 ohm world, why not just always use 50 ohm lines for interconnection, unless you are specifically trying to do impedance matching. There are software tools (and hey, even slide-rule sorts of calculators) available to help with all this...Reg has some programs on his site, which are fine if you like non-graphical interfaces. I prefer programs like RFSim99 (free) and WinSmith (not free, but there are other free similar reflection-coefficient based programs) that have graphics, which helps me visualize what's going on.

Cheers,
Tom

I was doing it from memory, Tom, which may be faulty. As I
remember, you coil was 2" dia and 100 turns at 8 TPI. If
that's not right, what was it?

> http://www.w8ji.com/agreeing_measurements.htm
> Roy's first. You're way down the list Gene. Get back in line.

Telling Roy about his abortive use of standing wave current
phase to try to measure phase shift when there is zero phase
shift in a wire or in a coil is just stating the technical facts.

As far as measuring phase through a coil goes, neither you
nor W7EL has any clue as to how to make valid measurements.
You guys really need to listen to Gene Fuller who said:

Regarding the cos(kz)*cos(wt) term in a standing wave:

> Gene Fuller, W4SZ wrote:
>> In a standing wave antenna problem, such as the one you describe, there is no
>> remaining phase information. Any specific phase characteristics of the traveling
>> waves died out when the startup transients died out.
>>
>> Phase is gone. Kaput. Vanished. Cannot be recovered. Never to be seen again.
>>
>> The only "phase" remaining is the cos (kz) term, which is really an amplitude
>> description, not a phase. The so-called "phase reversal" in longer antennas is
>> not really about phase either. It is merely a representation of the periodic
>> sign reversal seen in a cosine function.

What is it about Gene's posting that you and W7EL don't understand?

52 feet of wire on 4 MHz is 0.21 WL. Dr. Corum says anything
over 0.17 WL requires the distributed network model.

The 3 nS delay measured by W8JI through that coil is simply
technically impossible except in his mind.

Hi, Richard -

Although your language is a bit formal for me (I lack a formal education), I think I understand what your are saying. I am aware that the fields caused by the differential currents cancel (mostly). It makes sense that a magnetic core is not necessary when the fields cancel. And, I can see where the core is useful when the fields do not cancel. I just did not interpret Reg's information as applying to one situation and not the other.

Thank you and 73.

John

Sounds like your argument is with Dr. Corum, not with me.
He said: "In fact, lumped-element circuit theory inherently
employs the cosmological presupposition that the speed of
light is infinite, as every EE sophmore should know. ...
Lumped element representations for coils REQUIRE that the
current is uniformly distributed along the coil - no wave
interference and no standing waves can be present on lumped
elements. ... Lumped circuit theory fails because it's a
THEORY whose presuppositions are inadequate."

Perhaps you missed that day in EE203?

Why, yes, in fact it is true that I don't agree in every case with the unknown guru you've placed on a pedestal above all reproach. So there. It is also true that I do not agree with your (mis)interpretation of what your unknown guru has written.

I REGULARLY model transmission lines as "lumped elements" and do NOT "presuppose that the speed of light" through them is infinite.

I REGULARLY model op amps as "lumped elements" and do NOT presuppose that the phase shift (and therefore propagation time) through them is infinite.

I REGULARLY model analog to digital converters as "lumped elements" and do NOT presuppose that the result comes out at the same time as the signal that goes in.

I REGULARLY model inductors as "lumped elements", and do not presuppose that they have no resistances and capacitances parasitic to their inductANCE.

I find that my models very reliably predict the behaviour I actually observe in the circuits I build. I am served very well by the models I use.

By the way, what's EE203? It's very likely that I missed not only that day but all such days. You yourself may well be presupposing something that isn't true.

Cheers,
Tom

I do wish you guys would argue in good faith.

STRAWMAN ALERT
I didn't say there was no capacitance to the outside world. I said
such is a secondary effect, not a primary effect, and for the sake
of the present argument, can be ignored as secondary effects often
are ignored.

> Because of that YOUR model has, guess what, ZERO time delay along the
> coil.

No, transmission lines have negligible capacitance to the outside
world and their time delays are NOT zero. You straw man is just
not believable.

> It is ONLY through a combination of both inductance AND capacitance
> that you get propagation velocities equal to or less than the speed of
> light.

Yes, and that capacitance can be either internal or external.
I'm ignoring the rest of your posting because it is based on
the false premises of your straw man. But you get an 'A' in
Obfuscation 101.

> It amazes me that you fought so hard for a distributed model in which
> that capacitance to the outside world is missing, ...

It is *NOT* missing. That is just your straw man. It is just
secondary to the addition of the forward and reflected current
phasors.

At a point where the the forward and reflected current phasors
add up to zero, it's hard for anything else to contribute much
of an effect.

Then you are somehow applying a patch to the lumped element model.
The basic lumped element model assumes no resistance and no
capacitance. That's how the lumped inductance-only works in EZNEC.

> I find that my models very reliably predict the behaviour I actually
> observe in the circuits I build. I am served very well by the models I

I saw a construction article in the ARRL Antenna Handbook , 13th Edition, 1980 on page 247-249. I also did some google searchs and there was a thesis paper on this very same article in the 1990's where two people modeled the antenna described in the Antenna Handbook and said there were errors in the article. I could not get the complete paper that would have gone into the details.

I have built one of these antennas for the 850 mHz range using rigid coax per the article in the ARRL Handbook (with 7 half wave elements, and two 1/4 wave elements per the article) and saw poorer performance compared to a small 1/4 whip antenna connnected to the back of the radio. Not sure what went wrong.

Comments??

Tnx

Of course not. There have been a myriad of coils twisted through this thread and I specifically selected the one that started this epic: the subject of Yuri's investigation (2ï¿½" by 10").

>The length to diameter ratio is 6.
>H = .92
>D = 5 cm
>
>HD = 4.6 pF by the formula on page 451 of the "Radiotron Designer`s
>Handbook". Course, formulas are a dime a dozen and disputed.

Hi Richard,

And by virtue of their being offered renders the dismissal of "approaching zero" as cavalier.

And this was "Self Capacitance" and not distributed capacitance? It seems to me that any formula for capacitance that neglects the discussion of surface area must be a very crude estimate. Are we to believe that a coil of
H = .92mm
D = 5 mm
wound with #44 wire has the same 4.6 pF of Self Capacitance?

I can see the dime's worth of value and the source of dispute. Perhaps there is more commentary to be found on page 451 that resolves this and elevates the dime's worth both.

Going further, if I take your coil and merely set the turns count to 18.4, then the coil will self resonate in the 20M band. The capacitance you computed is not very trivial for HF.

Cecil, there are two Corums and they're both Tesla coil
crackpots. Secondly, Tom is right, you have to have capacitance
to somewhere or your transmission line analogy becomes mired in
absurdities. Third, it isn't enough to think something up in
your head to make a convincing theory, you have to be able to

predict behavior with it. Finally, you have to understand your subject before you even start thinking. I'm surprised you didn't even take the time to make a real coil and at least try to determine its characteristics before wasting everyone's time by starting this thread.

Would you guys please stop implying falsehoods and make an
attempt to argue in good faith? I didn't say the capacitance
didn't exist. I said it was a secondary effect to the superposition
of the forward and reflected waves. That you are forced to twist
what I said speaks volumes about your argument. Why don't you feel
secure enough in your technical argument not to have to twist my
words into something I didn't say?

> Third, it isn't enough to think something up in
> your head to make a convincing theory, you have to be able to

I have predicted behavior on http://www.qsl.net/w5dxp/current.htm
with text surrounding http://www.qsl.net/w5dxp/1WLDIP.GIF. That
graphic is not disembodied as you claimed. It is surrounded with
examples and text, more than enough proof for any rational person.

The current at each end of a coil obviously depends upon where it
is installed in the standing wave antenna system. Your wearing of
blinders doesn't hide that technical fact from anyone except yourself.

Uhhhh Richard, those weren't measurements. Those were calculated
results, using formulas out of books. The only measurements that
I have made were of 1. self-resonant frequencies within the
accuracy of an MFJ-259B and 2. standing wave phase measurements
that agree with Kraus and EZNEC. The 59% accuracy was in my
wild ass *guesses* as opposed to the 207% error in W8JI's phase
measurements.

> the context of what I say.

The real problem is your concept that "current is current",
implying that there is some sort of identity between all
kinds of current. Is DC current identical to RF current?
If not, your "current is current" statement is incorrect.
There are different flavors of current. DC Vs RF is just
one.

Standing wave current Vs traveling wave current is another.
That you don't see the difference between func(kx)*func(wt)
and func(kx +/- wt) is the entire problem. Why are you so
unwilling to discuss that narrow technical topic?

If you would discuss that problem, you might wind up winning
the rest of the argument but you will never know until you do.

Hi, Richard -

I am afraid I do not understand the meaning of "bafflegab". I take it to be a derogatory term indicating that the posting person believes the monologue to be unbelievable. Or something like that. Wikipedia has nothing on the meaning of this word. A search of Dictionary.com produces Gobbledygook which is no help at all. Another search on Dictionary.com of Gobbledygook results in "Unclear, wordy jargon." Is this what is meant?

Thanks,
John

>I am afraid I do not understand the meaning of "bafflegab".

Hi John,

It is a term of invention by the greatest practitioner of that art -
Reggie, of course! He introduces nearly every example of it with the
term nestled in his post like a road side flare. Bafflegab is what
was written before you (the second poster to answer) got your say in.

There are similar usage examples of his with "gurus," a term that was
not coined by him, but similarly littered in postings for effect in
his (and imitators') attempts in social climbing. "Gurus" are those
who got to say it first.

So, in the pecking order of it all, "gurus" write "bafflegab" -
unless, of course, you posted first. As a strategic variation on this
theme, there is the inverted-guru-gambit that is something like en
passant. That is, you don't post an answer even if you do manage to
be first, you post how it will be answered wrong by others who you
claim to be gurus.

Reggie has been most influential in these stylistic touches and more
than a few correspondents ape his method. Unfortunately, this also
reveals how quickly novelty descends into clichï¿½; and how wikipedia
trails in social currency.

Also, consider that this is a GAIN antenna (a misnomer, as the "gain"
is created, by takeing power from somewhere else!). This means that the
radiation patern is on the horizon, tho, say 15 degrees above, or below
THAT horizon, the radiation from that "gain antenna" may be a LOSS! and
it gets worse, at higher angles! Kinda like aiming a yagi at a (say , 20
degree angle above (or below) the horizon, wouldn't expect to have a
full signal, if the SOURCE were on the horizon, would you)? A 1/4 wave
whip is much more forgiveing at higher angles of radiation0, while your
"GAIN" antenna has a pattern like a doughnut (power concentrated on
the horizon, limited radiation at angles above, and below that horizon).
This can be a problem in mountainous territory,where a 1/4 wave whip
will out-perform a gain antenna for coverage. As info, Jim NN7K

just read a article someplace about a new conductive paint that is going to be used by different sources (pvt/mil) to in effect paint an antenna on a surface. once such use was an 'orbiting' blimp , planes etc to repete signals

ok so i wonder my roof has a flat brick wall it's 40ft tall 40ft wide

if i painted a antenna design think i'd get any useful performance in at least one direction?

unf it didn't state any spec's but it's commercial

just really thinking out louad how a antenna w/little profile but otherwise large surfacce area might work

Sorry, Reg didn't invent the word. It's been around for more than
half a century.

"Bafflegab - This word hit the newspapers and public notice on 19 January
1952, the day after a plaque was presented to its inventor to mark his
creation of this invaluable word. He was Milton A Smith, assistant general
counsel for the US Chamber of Commerce."

surprized that nobody mentioned the sgc tungers i've been using 2 for
quite some time the mac200 and a sgc237

it tunes all bands/modes a tiny short dipole that i am using down to
never more than 1.2swr tunes in a sec or so and well the 237 is
mostly quite, but being roof mounted moot point

the mac200 has usual relay noise on initial tune, brief click after but
has way cool 4way antenna switch and swr /pwr meters!!

and they tune w/rf by themselfs not that it's unique

i also use ldg great stuff these 2 firms seem to kinda corner the
market

My SGC-230 will tune everything including no antenna
at all. I once forgot to install the coil and stinger
on my mobile antenna. The SGC-230 faithfully tuned the
three foot bottom section to resonance on 75m. :-)

Hi Jim

A properly done colinear array of 8 half wave elements will sure have a
highly directive pattern in the Elevation plane. With some luck and low
loss components you might get 8 or 9 dBi. But, the pattern will have a
pattern max thats broadside to the axis of the colinear array at only one
frequency. That pattern max will squint up and down (with respect to the
horizon) as the frequency varies from that center frequency.
I'd bet that you will be able to realize appreciable dirrectivity from an
array of 7 lengths of RG-6 with 2 quarterwave added elements. But,
developing the array to provide low VSWR and best squint angle at any chosen
frequency will demant some "field testing".
You probably already knew that. I just wasnt sure. Besides I have wasted
alot of time developing a very similar colinear array for commercial use.

Actually if the paint is continuous in it's conductivity there is no
reason why a painted antenna picture would not work. Tuning it might be
problematic but would work.
Try it and report back.

I would suppose that under the right conditions an antenna like this could perform reasonably well if it were properly set up and I can see how getting consistent results would be difficult. This would leave some people to swear by it while other swear at it.

82. Coils and Transmission Lines.

Newsgroup: rec.radio.amateur.antenna

NOW AVAILABLE ** New Program "TRANCO_1.exe"

This program analyses performance as a transmission line, of a
single-layer solenoid coil which may be inserted in an antenna wire.
The coil itself may be used as a very short vertical antenna at its
1/4-wave resonant frequency.

From the input data of length, diameter and number of turns, the
program calculates inductance, capacitance and resistance of the
equivalent transmission line. The secondary constants of
characteristic impedance Zo, phase shift, velocity factor, and
attenuation are calculated. Also the feedpoint input impedance, R+jX,
for when a coil is used as an antenna.

Because of the sensitivity to the environment of such an antenna and
its high Q it will be necessary to trim antenna length to a particular
wanted resonant frequency.

Download TRANCO_1 in a few seconds from website below and run
immediately. Filesize = 38 Kbytes. (It's at the bottom of the list.)

Jim,

Thanks for info. You are correct as I do live in "hilly" area. I raised
the antenna up to 30 feet and there was a big difference in signal strength.
I do not have equiment to measure the difference accurately, but on an Icom
R-7000 there was 1 s unit (or so) difference but there was much lower noise
and better readability.

Thanks again

John, what with the unwanted interference from Richard Clark, you'll just have to accept the fact that the ferrite material has little or no effect on transmission through the short length of transmission line, be it coax or twin-line, wound on the ferrite core.

I can only repeat that, insofar as the normal transmission current is concerned, the currents in the pair of wires flow in opposite directions and therefore neutralise each other. No flux is induced in the ferrite.

The unwanted longitudinal current flows equally and in the same direction along both wires and therefore comes under the influence of the choke.

It is all so beautifully simple!

Reg.

I guess I should have been a little more specific. Since I live in an antenna restricted community, I have been able to install (stealth) 360 ft loop, half of which is on my roof (wire thru TV insulated standoffs), and the rest of the loop in my attic, fed with RG8U at the center connector. Because of where the center connector of the antenna, and where my rig is located, I have to run approx, 70ft of coax feed. I am currently using an MFJ949 manual tuner, but that is getting to be a real pain when band switching at the transmitter, and am seeing approx 1.5:1 across all the bands, but I am sure that if I could remote the tuner to the center connector, I would get a better match.

i have a uhf tv antenna on my balcony. i am getting ghosting.

i think the ghosting is from signals bouncing off the balcony wall and hitting the antenna a second time.

apart from building a 100' tower to raise my antenna into the open sky, is there any way to keep the wall from reflecting ? can i put some sort of foil behind the antenna to block it out ?or cover the wall with some non reflective material?

thx

Jimmie,

There have been, and will continue to be - a lot of discussions about the EH-Antenna. Some of the discussions are bordering to physical wars and other postings are just plain simple stupid. As usual in other words...

One of the thing that are once and for all settled is that the antenna function does not rely on coupling to other metallic objects. That myth is so totally debunked so I won't even go there. Another fight is regarding the efficiency.

The current discussions surrounding the EH is about any possible phase shift as the main reason for the function.

If you are interested inthe EH-Antenna for hamradio use, browse to www.eh-antenna.com. If you intend to use it commecially, it's patended and you need to buy a license or a ready made antenna.
The EH is used for RFID and for vehicle communication as well as telemetry. The ham EH's are only a very small fraction of the market.

And no, I don't think your friend made up an EH antenna.

There are some tests done in Radcom and possibly other ham magazines.

The EH-Antenna is just another small antenna with it's preferred field of application. It's not to be compared with any directional antenna as it's mostly omnidirectional. Also, the EH have to be mounted 1/4 wavelength up to work according to the designers.

The EH that receives most of the appraisal is the 160m version. Probably because it's very difficult to have a dipole or longwire up for 160m... so when compared to a 160m dipole 10 meter above ground, the EH outperforms that dipole... When comparing antennas close to ground, it's often a case of "the least worse" functioning antenna and the EH performance is reported to deteriorate lesser than wire antennas when close to ground and have a better S/N.

The VHF EH's outperforms most typical VHF omnidirectional antennas even i the difference in size is not that great compared to traditional antennas.

Very few hams are neutral in the view of the EH antenna so be prepared to whip up a storm if you build one and claim success or failure.

BTW! If you intend to try for yourself, do not use ferrous material for the build. That will bring down the resulting bandwidth by 70% or so!

Also, a dipole or wire antenna gives you a multiband antenna, especially with an antenna tuner.
The EH is a single band antenna only and cannot be tweaked by an antenna tuner. For a complete coverage of the HF ham bands you need many antennas.

Cheers

Dan / M0DFI

There is a big problem with that idea because common brick absorbes
water content and will provide a very lossy substrate.
The resonant frequency will also be affected due to capacitance.

An r-f reflection capable of producing a ghost in an analog TV broadcast signal needs to have something like a 1/2 microsecond minimum propagation delay from the direct signal. That takes a path difference of ~492 feet, so your balcony wall probably is not be the source of your ghost.

More likely it is from a reflecting surface (building, sign, water tower, etc) somewhere near the direct path from the TV tx to your antenna. You might try a corner reflector or yagi, and aim it in various directions (not necessarily toward the TV tx) looking a for a cleaner overall signal.

The EH antenna theory is total rubbish. It is physically impossible to
mix an electric field and a magnetic field and generate EM radation.

The basic operating premise of the EH antenna is a lie.

> The EH that receives most of the appraisal is the 160m version. Probably
> because it's very difficult to have a dipole or longwire up for 160m... so
> when compared to a 160m dipole 10 meter above ground, the EH outperforms
> that dipole

Nonsense. You won't find a single scientifically made test where an EH
antenna outperforms a similar size regular short monopole.

On 160 meters EH antennas are typically 10 dB down or more from very
poor dipoles.

If an EH antenna beats another antenna it is always tracible back to
the other antenna being grossly poor. There isn't a single professional
evaluation of the EH antenna in the world that has ever shown it to be
better than any other antenna the same physical size, and most show it
is actually worse.

If you polled a large cross section of people about a very poor leader
of a country, you'd find a significant percentage claiming the very
poor leader was a good leader despite very clear evidence to the
contrary. The EH antenna and any other widespread myth is no different.
It's all about blind faith and spin rather than facts. Some people just
don't care about facts, and prefer to live by faith.

The EH antenna will probably go on for years, despite the fact it has
been proven over and over to be a fraud.

> horizon) as the frequency varies from that center frequency.

The change with frequency in the angle of the elevation pattern maximum field is the result of the varying relative r-f phase vs the operating frequency that is applied to the radiating elements in this design.

This can be eliminated by using a vertically stacked array of identical radiators fed via an n-way power divider, whose output connects to feed cables of equal electical lengths to each element of the array. The directivity (gain) and sidelobe distribution of this type of array will change with operating frequency, but the elevation angle at which the peak field is directed will remain the same, regardless of the input frequency.

This approach is used in broadcast transmit antenna designs giving good signal coverage over large sections of the UHF TV band, or the entire FM band.

The nature of traveling wave current and standing wave current
is different. Does your program take that into account?

The "current through coils" argument boils down to the ones who
understand standing wave currents in a standing wave antenna and
those who refuse to take the time to understand.

Quoting "Optics", by Hecht: "E(x,t) = 2Eo*sin(kx)*cos(wt)
This is the equation for a STANDING or STATIONARY WAVE, as
opposed to a traveling wave (Fig. 7.10). Its profile does
not move through space. ... [The phase] doesn't rotate at
all, and the resultant wave it represents doesn't progress
through space - it's a standing wave."

Until the gurus take the time to understand the nature of
standing waves in standing waves antennas, they will keep
committing the same mental blunders over and over.

Hi Richard

Do you have a sketch of the harness a guy might use to feed that 8 dipole
colinear array? Remember, this colinear antenna is mounted on the back of
a Lap Top Computer for WiFi use.

So, the subject is still taboo.

Well Tom, I can't say I have seen your evidence that the EH-antenna is a fraud. On the other hand, the only test I found of the 160m EH was in the RSGB Radcom, and that test was in positive wording. I have not seen any positive test of a 80 m EH tho'!
Also, a couple of tests that I've seen on the EH claiming it doesn't work, have been rubbish too. I saw one test by a chap - Calvin something I think it was, that had all the necessary equipment at hand but unfortunately, the test where spoiled by to inflated ego's. Other tests have been claimed it do work but I don't see any of them as really scientifically correct either.

Professional tests? Wasn't there a proper evaluation done on a commercial EH for a radiostation a couple years back?

I do not agree with you claim that there isn't a single professional evaluation. The EH for VHF was tested in France - maybe two years ago now and was in line for 27,000 installations. The EH lost because of the price, not because of performance. The EH results gave a S/N improvement of 5 to 7 dB, which dramatically improved the telemetry systems functionality. As this was a commercial evaluation, no data where released.

As to the field theory, which I didn't mention anything about in my earlier posting, I just cannot comment about that theory as I, amongst many other hams, lack the really deep knowledge of EM theory other than what can be found in the normal text books.

The let us take a look on the "fraud theory". The inventor of the EH doesn't have (as far as I know) any known record of fraud. On the contrary actually. As I remember it, a similar debate raged when he presented the mini magnetic loops some years ago. When he presented the noise bridge, there where no problems at all as I remember it. So for now, I can't see any deeper conspiracy theories lurking around the corner neither any real reasons as an incentive for a fraud.

The best tests of the EH so far have been on VHF and without any coax connected to the EH.

I'm actually very interested to read up on this and as you write there are multiple evidence of fraud, I'm sure you can post some pointers to these tests.

BTW! I'm quite sure many of us stumble on the EH's daily nowadays as a common use of the EH is for RFID equipment.

Cheers

Dan

>elaborations about real-life coils will not be valid either.
>

Evidently I was in too much of a hurry to leave for the GMDX convention,
because what I mean to write next was:

"Cecil's theory does not work for this test case, "

[I definitely did type the word "not", but it accidentally disappeared
from the version that was posted.]

So, from the top of the paragraph:

Cecil's theory does not work for this test case,
>because it requires that basic electrical properties like current and
>inductance switch into a different kind of behaviour in what he calls a
>"standing wave environment". But it is an absolutely basic fact that
>the physical world does NOT change its behaviour according to the way
>we choose to think about it. If any theory requires that, it's an
>absolute proof that such theory is false.
>
>
>For the avoidance of doubt (as they say in Scottish legal documents):
>It certainly IS possible to analyse and predict the behaviour of
>coil-loaded antennas in terms of travelling and standing waves. My
>objection is specifically against Cecil's method, which is provably
>incorrect.

Sorry for any confusion that typo may have caused. This corrected
version is now fully consistent with what I meant to say.

Hecht forgot to put the phase difference in his formula.
It's no wonder there's no phase information in your
standing waves, Cecil, Hecht left it out. Not only
that, but where did he get the idea that it was sin(kx) instead
of cos(kx). I understand Hecht is a good old boy, but I'd like to
see his derivations.

More astonishing than that, Until the "gurus" put their finger on the coil, or aquarium thermometer, or RF ammeter, or infrared scope and see that the loading coil (in a typical quarter wave resonant whip) is heating up at the bottom, being the reality that defies their "scientwific theories why it shouldn't" - they will keep committing the same mental blunders over and over.

What's next? There is less current in a wire (coil) where wire (coil) gets hotter?
Let the games begin!

Thermometers don't lie, meters don't lie, even EZNEC shows it! So wasaaaaap?

Yuri, K3BU

112. What this, The Jim black balun ?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-04-02 16:18:21 UTC
From: tucker@conninc.com
Message-ID: <1143994701.455481.269970@v46g2000cwv.googlegroups.com>
Source record: 61754

I found this at a flea market today, it looks a typical PVC balun with so239 female on the bottom but has 35-50 foot length of 300 ohm twin lead TV cable coming out the other end, it says:

The Jim Black Balun
air wound 2kw pep
with low swr
1.8 - 30mhz 1:1 ratio
by wa4ytu - Jim Black

it looks like you hook your coax to the female connector, but how do uoy rrun the 300ohm
twinlead? horizonal, vertical or does it have to be cut to length? I cant find any instructions
on the web for this balun/antenna.

Source record: 61755

I have the Ultralite Senior and it seems to work pretty good. I originally bought it just for local work and to be able to cover all bands. I put it up 30 feet in some trees and since my yard is too small the ends hang down about 15 feet. I used a 4:1 balun with the full 100 ft. of ladder line it comes with and then about 75 ft. of coax to my radio.
It loads up with my TS-480 auto tuner on all bands.
I now use it for DX as much as my vertical and my half squares. It is a lot quieter than the verticals. I worked Peter One from N. California on 20 meters and New Guinea on 15 meters with 100 watts. It even works on 6 meters, though no where near as good as my stacked loops.

are two places.

http://www.w8ji.com/e-h_antenna.htm

> Professional tests? Wasn't there a proper evaluation done on a commercial EH
> for a radiostation a couple years back?

This is what speaks volumes about the credibility of the CFA and EH
antenna people.

They keep claiming they will soon have supporting data, but it never
appears. There always is a reason, like the "test is secret".

Common sense would tell anyone that if they are on to something, they
would just pony-up the cash to have a reputable lab do a test. If you
think about it, there isn't a single invention in the world good for
common man that actually works where the manufacturer can't point you
at working examples that can been seen by people.

This EH stuff is exactly like the 1969 L-88 Corvette that was sitting
in the mother's garage since Viet Nam, sold to a friend of the guy
telling the story for $250.

> I do not agree with you claim that there isn't a single professional

Then you'll have to take my word and other people's word for it. We
cannot synthesize radiation.

See:
http://www.w8ji.com/radiation_and_fields.htm

> The let us take a look on the "fraud theory". The inventor of the EH doesn't
> have (as far as I know) any known record of fraud.

1.) Ted Hart told the Atlanta Radio Club he invented or designed the
MFJ loop antenna and MFJ antenna analyzer.

2.) An officer of that club conatcted me, and asked me if that was
true.

3.) I told them no, he had nothing to do with those products and I
didn't even know who he was.

4). Ted Hart then told Antennex I "quit the Atlanta radio club" and
"stormed out of a meeting". Antennex published that letter.

I have never been a member of ARC.
I have never in my life attended a meeting of that club.
I have never quit any radio club in my life.
I have never stormed out of a meeting of any kind in my life.
Ted Hart had nothing to do with the MFJ loop or the MFJ antenna
analyzer.

Yuri,

No one I have seen has every said one tuern can't get hotter than
another turn in a loading coil.

For example, I can take a piece of airdux and short a single turn
anywhere in the coil. That turn and the turns around it will get very
hot, often even melting the form and discoloring the wire, even with
modest power applied in a resoant circuit.

I had my 75 watt Novice rig melt miniductor in certain spots way back
in the very early 60's.

The problem is wild theories are created from small grains of truth or
factoids. It is the wild theories that people question.

In an effort to support the wild claims, there seems to be an effort to
dismiss anything but the wild theories. Here is how it goes:

1.) My Hustler antenna loading coil (known to be a poor electrical
design) melted the heatshrink at the bottom

2.) This must be becuase there is only high current at the bottom of
every loading coil.

3.) This must be because the standing waves on the antenna all wind up
in the loading coil.

4.) This must mean all loading coils act just like they are the x
degrees of antenna they replace.

5.) This is why, no matter what we do with loading coil Q, efficiency
doesn't change much.

6.) We will write a IEEE paper about this astounding fact, since all
the texbooks about loading coils or inductors in general must be wrong

7.) Anyone who point out it is imperfections in the design of the
system that cause this must be wrong, since I saw the coil get hot

8.) Anyone who disagrees with me must think himself a guru, and be incapable of learning or understanding how things work

9.) I know all this because the bottom of the coil gets hot in my antenna

What's next? There is less current in a wire (coil) where wire (coil) gets
> hotter?
> Thermometers don't lie, meters don't lie, even EZNEC shows it! So wasaaaaap?

It's all been explained over and over again.

If the termination impedance of the coil is very high compared to shunting impedances inside the coil to the outside world, a coil can have phase shift in current at each terminal and it can have uneven current distribution.

This is not caused by standing waves or "electrical degrees" the coil replaces, but rather by the displacement currents which can provide a path for the through currents.

Reg actually explained this very well, as has Roy, Tom D, Gene, Tom ITM, Ian, and a half dozen others.

The reason you keep beating your head against the wall is you want to think the conclusions you formed were correct.

If I wanted to design a loading coil that has virtually 100% current taper, I could. If I wanted to design one with virtually no taper, I could. I could actually have an antenna of a fixed height and by making various styles of loading coils go anywhere from nearly uniform distribution at each end of the coil to some significant taper.

The problem is Cecil attributes it all to standing waves, and not to the inductor's design. You seem to be doing the same.

Since we won't agree with your wrong theories, you then conclude we are saying step one is wrong and you never saw what you saw. Step one is fine. Step two is where everything you say falls apart.

>Thermometers don't lie, meters don't lie, even EZNEC shows it! So wasaaaaap?

If you're looking for an argument, you're looking in the wrong place.

Nobody denies the raw evidence, like the fact that some loading coils
get hotter at the bottom than at the top... and the fact that some other
coils don't (or nowhere near as much).

There are good explanations for everything you see. But the only valid
explanations are the ones that account for *all* the facts about *all*
types of loading coils.

The argument is specifically about Cecil's attempts to explain the
evidence, using his own particular ideas about "standing wave antennas".
He makes it kinda work for the cases he wants to think about, but in
other cases it gets things fundamentally wrong - and that isn't good
enough.

There is no "Download Pascal source code from here" section on the Index page. There is a "Get Pascal source code from here" section which lists the following:

GRNDWAV3.pas * Groundwave propagation vs frequency, distance and terrain.

TOPHAT2.pas * Performance of top-capacitance loaded vertical.

PADMATCH.pas * T and Pi resistive-matching and minimum loss pads.

I do not see the TRANCO_1 source code listed.

The problem here is not "Current through coils". The problem
is that a lot of the gurus are completely ignorant of the
nature of standing wave current and refuse to alleviate
their ignorance.

I think the EH is the same idea as the CFA; in which case the following
paper
says it all: http://www.fi.uba.ar/materias/6654/download/CFAantenna.pdf.

It is hard to imagine going to these lengths to debunk nonsense, but I guess
it is the only way.

Richard,

One of the licensees are an Israeli supplier of RFID systems. You need to check on the www.e-antenna.com for any references to them.

The rubber duck antennas are mostly to sensitive to metallic objects in the proximity. There was actually good reasons to choose the EH but as the cost for a helical was counted in cents, a multi dollar cost for an EH replacement was a definitively showstopper.

The claim to be cheap could probably be true for a commercial AM transmitter as you need a significant lesser amount of property to house it.

As I was writing about VHF antennas, the amount of property needed is not really anything to do with cost...

The other comments from you Richard, went into the bin as just stupid remarks and not really productive - merely as it tends to be on Usenet...

I've seen to much weirdness in the debate surrounding the EH's but I have to admit that the CFA is something I'd rather avoid spending time on...

Unfortunately, the debate in this matter tends to go religious and that excludes any real possibility to neither debunk nor confirm the EH. Pity.

So Jimmy,

By firing of questions about EH's you will really stir up a hornets nest...

Cheers

Dan / M0DFI

Well there you have it, folks. Gurus don't even make typo mistakes.
Some evil server removed that "not" on purpose from Ian's posting.

> Cecil's theory does not work for this test case,
>> because it requires that basic electrical properties like current and
>> inductance switch into a different kind of behaviour in what he calls
>> a "standing wave environment".

RF current switches from a different kind of behavior than DC current.
Phase, capacitance, inductance, and wavelength all have to be taken
into account in the steady-state analysis. That is a technical fact
that I'm sure you appreciate.

Why is it such a stretch to recognize that standing wave current behaves
differently from traveling wave current? That standing wave current is
different from traveling wave current is readily apparent from the
equations. In the following equations, 'K' is used for a constant,
'z' is the linear distance up and down the line, and 'w' is omega.

Forward traveling wave current = K1*cos(kz+wt)
Reflected traveling wave current = K2*cos(kz-wt)
Standing wave current =
K1*cos(kz+wt) + K2*cos(kz-wt) = K3*cos(kz)*cos(wt)

If tK1 = K2, then the standing wave doesn't move. Please dust off
your old math books and realize what the above equations imply at
a physical level.

>> description, not a phase.

> Not only
> that, but where did he get the idea that it was sin(kx) instead
> of cos(kx). I understand Hecht is a good old boy, but I'd like to
> see his derivations.

Apparently, you are ignorant of the difference in conventions between
optics and RF engineering. In optics, there is no current so there is
no current changing phase at an open circuit. In optics, the M-field
changes directions but not phase. In RF engineering, a change in
direction of the H-field is considered to be a 180 degree phase shift.
Both conventions are correct as long as one understands them. Your
strange statement about Hecht above just proves your ignorance.

It is caused by where the coil is installed in the standing wave
environment, proved on my web page at:
http://www.qsl.net/w5dxp/current.htm

That the proof is accurate explains why you refuse to discuss the
technical facts surrounding it.

> The problem is Cecil attributes it all to standing waves, and not to
> the inductor's design.

Given the fixed design of a single inductor example, I can change
which end the current is highest by simply placing in in the proper
place in the standing wave environment, the environment that you
refuse to discuss.

Hi Dan,

That's worse than vanity publishing. At least hard copy publishers
limit their quota of goof-ball articles due to the cost of ink.
Anyway, an Israeli supplier is hardly the end-all be-all on this
topic.

>The rubber duck antennas are mostly to sensitive to metallic objects in the
>proximity. There was actually good reasons to choose the EH but as the cost
>for a helical was counted in cents, a multi dollar cost for an EH

Telling us "good reasons" were nixed by something else passes an
ocean's worth of water under the bridge. In the old days (and
possibly still) girls who didn't care for certain fellow's invitations
would put them off by saying they were washing their hair that night.

I'm afraid the eh/cfa/what-have-you are as plug ugly as that fellow,
but "something" has to be said so as to not hurt feelings.

>The claim to be cheap could probably be true for a commercial AM transmitter
>as you need a significant lesser amount of property to house it.

You are suggesting that antenna economy doesn't scale with decrease of
wavelength? Odd. You still have the same building either way.

>As I was writing about VHF antennas, the amount of property needed is not
>really anything to do with cost...

A resistor in the air makes VHF contacts too.

>Unfortunately, the debate in this matter tends to go religious and that
>excludes any real possibility to neither debunk nor confirm the EH. Pity.

You dismiss my comments as stupid, but you chose to respond to them
instead of Tom's professional testing results. That speaks a good
deal about religious affiliation.

You also skipped my technical discussion to focus on the
inconsequential. This is self-fulfilling about being stupid. There
are measured results out there that exhibit the eh as being a poor
performer compared to the short monopole it would compete with

(nevermind the full antenna it is supposed to replace).

Basically, if you cannot see the antenna, you can't hear it.
Fortunately you can stick anything in the air at VHF to compete on this basis. Unfortunately (for the eh/cfa/what-have-you) both the price and complexity don't stand a chance in competition with the rubber duckie - that's pretty stupid too.

What is this religion called?

Put a 1 inch wide piece of tape 33 feet long in the middle of that brick wall horizontally.

Paint the wall at least 5 feet wide totally around the tape.

Remove the tape.

Connect your coax approximately 15% from on end where the tape kept paint off the bricks. Then connect the braid to one edge where the tape was removed, then connect the center conductor directly across from the braid. Fasten the braid and center conductor.

Go downstairs and load up your 20 meter 'vertical' antenna.

AKA SLOT Antenna.

I suspect the paint might be expensive though!! :-)

> enough.

That's just not true, Ian. If the distributed network model agrees with the lumped circuit model, then the lumped circuit model is being used in an appropriate situation. If the distributed network model disagrees with the lumped circuit model, then the lumped circuit model is being used in an inappropriate situation. The distributed network model is always right when it disagrees with the lumped circuit model. The distributed network model is a *superset* of the lumped circuit model. To quote Dr. Corum:

"Distributed theory encompasses lumped circuits and always applies."

And before you dismiss Dr. Corum as a "crackpot", as others have, please pay attention to the references for his peer-reviewed paper published by the IEEE: Kraus, Terman, Ryder, Ramo & Whinnery, Born & Wolf.

The problem is that the lumped circuit model is being used in inappropriate situations because you and others do not understand how standing wave current in standing wave antennas differs from traveling wave current in traveling wave antennas. To compound the error, none of you are willing to discuss it from a technical standpoint. That unwillingness reeks of religion, not science.

Someone we both know and respect wonders why you are so closed minded. I suggested he contact you by email.

If you, or anyone else, were willing to discuss the nature of standing waves from a technical standpoint, most of the present argument would be resolved by that discussion. I'm willing to discuss it. Why aren't you?

It is entirely possible that I am abusing the distributed network model, but nobody will be able to prove it unless they engage in a discussion of standing waves.

Hello everyone!

I have just put my swl frequency database online. Please have a look at
http://www.swldatabase.com

Please send any feedback through the email that is listed on the page.
Thank you very much.

Reality check here. I need explanation how the above could happen. "Current stays the same ... and the big step increase in voltage." As far as "idiot" professors taught me, (current x voltage) = power. So, am I to discover that the pure inductance is better than perpetual motion amplifier of power? More power coming out of the coil than going in? Eureka!!! How could I overlook that? :-)

> As we go further up towards the top of the whip, current magnitude has to
> taper off to zero at the very top. This also means that the voltage

So it tapers across the straight piece of conductor, but not in the wound up conductor? Magine that! Reality check #2.

> Single-point loading by pure inductance has thus created almost all the
> major features that we see in a practical centre-loaded whip -
> particularly the big step change in voltage across the loading coil.
>

So the "teaching" is that there is a big step change in the voltage across the coil, but no-way change in the current? Who's law, theory, invention is that? (We are still talking about real RF currents, not "my voltage" and "your invincible, steady, unchengeable current"?)

> What we don't see in a practical antenna are exactly equal current

> that has no other complicating properties.
>

The whole argument is about REAL LIFE loading coil in the antennas. But you obviously ignored or not noticed that W9UCW also used toroid coil and found very similar results, about 40 - 60 % less current at the top end and NOT (just about) EQUAL as the arguments IS about. Who cares about or needs "pure" inductance? What for? Just to twist the argument that "gurus" were right? Gimme a break!

> If we can agree about pure inductive loading, we all have a firm place to
> stand. Then we can then put back those "other" complicating properties of
> a real-life loading coil, and see what difference they make.

As firm as driving my Buick in the free space!
Halooooo! Go measure it! See what it IS! Then if the coil IS hot at both ends, or you measure current almost equal at both ends, describe the experiment so we can verify it and we will rest our case and admit to be a bunch dummies stuck on stooooopid!
(We are still talking about quarter wave resonant, loaded typical mobile antenna with loading coil about 2/3 up the 8 - 10 foot mast, no detours to la-la pure inductance in the vacuum with no resistance, free space no-nothing thing :-)
And as Cecil mentioned, we are not disputing that there is no capacitance to the surroundings, or no losses through resistance and radiation amounting to SMALL (you put figure on it Richard) drop, versus more SIGNIFICANT (like 40 -60%) drop across the loading coil.

I am sorry to beeing away for a zilion of posts, but real life is more important and I am trying to be in touch. I will try to find the W8JI response to my first (start from scratch) post in order to find where I went wrong, if he will engage in some technical discussion. I hate to be wrong.

Happy second April foolsday!

Yuri, K3BU.us

> http://www.ifwtech.co.uk/g3sek

What "other two wires"? I see RF current flowing through one wire (base)
then another wire in series (coil) than another one in series (tip - whip)
then "finding" the tip, aka END reflecting form it, and going back, creating
standing wave with proper current AND voltage distribution according to sine
(or if you like cosine) function.
What about energy (power) conservation law? How can coil "make" more voltage
at the top, while "having" the same current on the top as at the bottom?

Whatever. I'd still like to see his derivations. In your case,
you're using the wrong equation anyway. What you really want is
Beta*l, or the radian length of your transmission line. You can
get that if you know, or can measure the usual parameters in the

transmission line impedance equation, using that equation to solve
for Beta*l. That won't prove your theory because you still haven't
shown that any one transmission line model is unique in terms of
substituting for your coil, but at least it'll give you something
to do.

Your professor would have told you that you "overlooked" the phase shift
in the voltage.

The rest is just more of the same kind of name-calling. You didn't
really read what I wrote, and you don't really want to hear any answers.
All you really want is a shouting match. Well, tough, you don't get one.

> I had my 75 watt Novice rig melt miniductor in certain spots way back
> in the very early 60's.
>

Stop right here. We are talking about perfectly good coil (Hustler 80m
resonator) no shorts between the turns, ne end effect shorting out turns
(and if so, then both ends are the same). Perfectly good coil, with wire
insulation intact, uniformly wound, uniform wire diameter (constant
resistance) good insulation, until wire gets red hot, and covered with what
appears to be heat shrink tubing.
When I applied about 600W to it, the coil obviously started to overhead,
with obvious tapered patter of heat distribution (no shorted turn culprit)
with most intense on the bottom, slowly tapering towrds the top. No signs of
similar "melting" at the top (to blame "shorted" turn from the top cap), nor
anywhere in the middle to indicate shorted turn.
If you do not believe that this could happen, than say so and I will provide
the evidence, I will melt another coil. If you believe and can relate some
of your melting to mirror this case, than please explain what else can cause
this besides the current being SIGNIFICANTLY higher at the bottom than at
the top.

What I know from the thermodynamics, that heat rises to the top. If the current was (almost) equal, then the coil would be heating up and starting to melt uniformly, with actually more pronounced effect at the top, due to the rising and adding heat from the lower part of the coil (no upside Buick here).
So lets talk specifics of the argument and not detours, please!

Maybe poor electrical design, but perfectly sound coil, with uniform insulated wire, wound on perfect cylinder. It was Hustler coil with its physical properties and heatshrink tubing over the turns that magnified the effect and attracted my attention.

So what is the reason? Isn't the higher current through the same resistance
wire cause of more heat development? We now why and Cecil explained it.
Depends where the coil is placed in the antenna and its place on the cosine
current distribution curve. It has been shown epxerimentally and also by
EZNEC when modeled properly as solenoid or loading stub. Yea, the "other"
zero size coils don't show that, EZNEC confirms that.

> There are good explanations for everything you see. But the only valid
> explanations are the ones that account for *all* the facts about *all*

We are talking about typical loading coils in typical antennas, no need to go to "all" that would skew that and "prove" it ain't so.

> The argument is specifically about Cecil's attempts to explain the

>

As far as I see, it is not just Cecil's own idea or discovery, he attempted to explain the obvious effect and in the process found that there is more support and standing wave theory by others. So we have an effect, and (close enough) explanation and way of modeling it (close enough), but have a bunch of people that cling to "she's flat".

> Whatever. I'd still like to see his derivations.

"Optics", by Hecht, 4th edition, page 289.

The intensity of a light beam is associated with the E-field
so Hecht's equations are in relation to the E-field.

Speaking of the light standing wave: "The composite
disturbance is then:

E = Eo[sin(kt+wt) + sin(kt-wt)]

Applying the indentity

sin A + sin B = 2 sin 1/2(A+B)*cos 1/2(A-B)

E(x,t) = 2*Eo*sin(kx)*cos(wt)"

Hecht says the standing wave "profile does not move through
space".

I have said the RF standing wave current profile does not move
through a wire.

Hecht says the standing wave phasor "doesn't rotate at all,
and the resultant wave it represents doesn't progress through
space - it's a standing wave."

I have said the same thing about the RF standing wave current
phasor.

Hecht says the standing wave transfers zero net energy. I have
said the same thing about RF standing waves.

As a data point, the results of modeling a coil as a lumped
inductor Vs a helical coil are NOT the same in EZNEC. EZNEC
disagrees with itself.

I am much more inclined to trust the helically modeled inductance
than the lumped inductance.

As Dr. Corum says: "Distributed theory encompasses lumped circuits
and always applies." In other words, the Distrubuted network model
is a superset of the lumped circuit model.

No, but I got cut off the NG by AOL's dropping NGs and therefore lost touch with the severity of the problem. Also got too busy with real life, which I considered more important and didn't even dream that this still would be the problem.
I though that some of the unbelievers would by now done it, saw it, realized they were wrong and confessed. Apparently not. So I am glad to be still around and will try to either get educated or contribute to setting the record straight and correct the fallacies that are out there.
Sooo, nobody would try to do the experiment and SEE it, but rather keep chasing the gay electron phasors charged with Kirchoffs through three way intersections and blame Bush for it?

Does this mean: "HERE WE GO AGAIN"?

I was taught that there is a 90 degree phase shift in an inductor. But, in a loading coil there must be less than 90 degree phase shift because the top portion of the antenna still has a small, ~3 to 5 degree, phase shift required to achieve resonance. So, does the inductance have a 90 degree phase shift or an approximate 85+ degree phase shift.

Voltage and current are in phase at the base and 90 degrees out of phase at the tip, at resonance, conclusion: less than 90 degree phase shift in the inductor. PLEASE EXPLAIN this physics anomaly!

:-)

True, but irrelevant. You are asking for RF current to switch its
behaviour while still being RF current.

>a physical level.

Let's try it a different way. At any point located a distance z along the antenna, there is the normal cyclical variation in current I with TIME, so:

I(t, z) = Ipk(z) cos(wt)

where Ipk(z) is the peak value of the current at point z. The cos(wt) term represents the cyclical time dependence of the back-and-forth movement of electrons; it has no dependence on z.

Ipk(z) is simply a scaling factor whose value depends only on the LOCATION of point z within the antenna. It has NO time dependence.

The next issue to describe how Ipk varies with the location z along the wire. The aim of antenna analysis is to find out what the current distribution along the wire(s) actually is. All the rest of the antenna's properties can be calculated from this.

Ipk(z) does not have to be a simple cosine function as you seem to assume above. A cosine function may be a good approximation for very simple (or simplified) cases; but when the antenna includes a physical discontinuity such as a loading coil, Ipk(z) will definitely NOT be a simple cosine function of distance z. So in general it will not be correct to bundle the z dependence into the same cosine function as (wt).

There are several methods of finding the current distribution. If you choose a method based on forward, reflected and standing waves (which can be done), the "standing wave" is simply a plot of Ipk as a function of location z. Ipk(z) is a scalar quantity representing the peak magnitude of the current, and its only dependence is on LOCATION. It is not an alternating RF current because it has no time dependence.

"Current" remains what it always was: simply the movement of charge (electrons). If it's an alternating RF current, the cos(wt) term describes how the charge moves cyclically forward and back past the observation point. A loading coil, the RF ammeter or the current-transformer measuring probe all respond to exactly the same cyclical back-and-forth movement of charge.

In the standing wave analysis, the current is still the net movement of charge, ie the instantaneous difference between the forward and reflected currents. These vary together in time according to cos(wt). It is not possible to measure the "wrong kind" of current by mistake, because there is only one kind.

Yep, when we try to argue the case, it ends up like this. So you know what I
read, but you would not want to explain, enlighten this "dummy" what is
going on, eh?
Uhm, the phase shift is different for current and different for voltage, or
you claim that current distribution curve would be way different from the

voltage distribution curve?
Can you draw the picture of current and voltage distribution in the case in question or provide the file for EZNEC or whateverNEC?

Got it!

I don't intend to - that quotation is perfectly correct. It means that in a test-case situation where the lumped model *does* apply, the distributed model will give EXACTLY the same results.

This is the test case that I'm trying to make you apply, to check that with a lumped-inductance load, your antenna theory predicts the correct behaviour, namely no phase shift in the current through a lumped inductance.

There's no problem with the distributed circuit model. There's no problem with the lumped circuit model as a subset of that. All the problems are with your incorrect application of those models.

The underlying problem is that you don't see the difference.

But if you feed a coaxial collinear at the center instead of at an end, the top and bottom portions will have tilts in opposite directions, and the maximum of the pattern will remain perpendicular to the axis of the antenna, at least over a broad range of frequencies. The gain will change, but not drastically; matching properly to the feedpoint over the range of frequencies is likely going to be the bigger issue.

And if the OP puts the gain antenna on a panel which can be tilted at various angles, the performance may well be far from what he really wants. I'd suggest a small stand of some sort that will keep the antenna in a fixed position, if the panel can move.

Cheers,
Tom

I already told you what is going on, the best and most accurate way I know. It isn't easy, and it took some time to make it concise and clear.

Your questions are based on a totally different way of looking at it, much of which I don't even accept as valid. Unfortunately that means I cannot answer them in any way that would make sense to me.

>Uhm, the phase shift is different for current and different for voltage,

If you mean the phase differences across the coil, then this is one I can answer: yes, that is exactly what I mean. The phase difference across the coil is quite small for the current but much larger for the voltage. This is normal behaviour for inductance. When current is being pushed through an inductance into a small capacitance, it generates a high voltage across the inductance, and also a large phase shift in that voltage. That is the dominant feature when the inductance of your real-life loading coil drives current into the relatively short top section of the whip.

>Can you draw the picture of current and voltage distribution in the case in
>question or provide the file for EZNEC or whateverNEC?

I did some drawings in a RadCom article - and we could certainly use a few diagrams here. It's late now and I have a tower to take down tomorrow... get back to you later.

Standing wave RF current does not exhibit the same behavior as traveling
wave RF current. If you understood the formulas, you would understand
my statement.

> where Ipk(z) is the peak value of the current at point z. The cos(wt)
> term represents the cyclical time dependence of the back-and-forth
> movement of electrons; it has no dependence on z.

Therefore, the phase of the standing wave current has no dependence
on z. In fact, for a 1/2WL thin-wire dipole the phase is fixed
at zero degrees no matter what is the value of z.

Moral: Standing wave current phase cannot be used to measure the
delay through a piece of wire, much less the delay through a coil.
But that's exactly what W7EL measured. Now do you see why those
measurements were meaningless?

THE PHASE OF THE CURRENT IN AND AROUND A LOADING COIL HAS NO DEPENDENCE
ON Z. Think about the implications of your statement.

> Ipk(z) is simply a scaling factor whose value depends only on the
> LOCATION of point z within the antenna. It has NO time dependence.

There is an Ipk1(z) at the bottom of the coil. There is an Ipk2(z)
at the top of the coil. Both of them have NO time dependence.
Therefore, the phase shift between them CANNOT be used to determine
the delay through a coil.

> The next issue to describe how Ipk varies with the location z along the

>
> Ipk(z) does not have to be a simple cosine function as you seem to
> assume above.

I do NOT assume a simple cosine function. I have said many times that
the fields of the loading coil warps the current waveform away from
the simple cosine function. It puts a bump in the cosine curve but

the fact remains that the current envelope magnitude contains the only phase information in the standing wave current. Above, you have essentially agreed with Gene Fuller that zero phase information exists in the standing wave current except in the magnitude.

> A cosine function may be a good approximation for very
> simple (or simplified) cases; but when the antenna includes a physical

I suggest that the standing wave current for each segment of the antenna can be plotted as has been done at:
http://www.k6mhe.com/n7ws/Loaded%20antennas.htm in figure 3
and that a cosine function can be plotted underneath that curve. Associating the bottom of the coil with one point on the cosine curve and the top of the coil with another point on the cosine curve will allow us to make a *rough* estimate of the delay through the coil. The cosine curve doesn't disappear - it is just warped by the current distribution through the coil.

> There are several methods of finding the current distribution. If you

Yet W7EL used that current with no time dependence to try to measure the delay through a coil. I don't recall you objecting.

> "Current" remains what it always was: simply the movement of charge

> observation point. A loading coil, the RF ammeter or the
> current-transformer measuring probe all respond to exactly the same
> cyclical back-and-forth movement of charge.

Yes, but two RF ammeters gives us a different and more complete view of reality. In a traveling wave antenna, the two RF ammeters would read the same value. In a standing wave antenna, the values read by the two RF ammeters depend upon where they are located. In the 1WL standing wave antenna at: http://www.qsl.net/w5dxp/1WLDIP.GIF, an RF ammeter located at point B might read one amp. An identical RF ammeter located at point D will read zero amps.

> In the standing wave analysis, the current is still the net movement of
> charge, ie the instantaneous difference between the forward and
> reflected currents.

There is no net transfer of energy in a pure standing wave. As Hecht says: "Its profile does not move through space." Nor does it move through a wire. Here's the above 1WLDIP.GIF wire replaced

by a loading coil.

```
|----1/4WL---|-1/4WL-|----------1/2WL------------|

------A------B-/////-D-------------fp-------------
```

An RF ammeter placed at B may read one amp. An identical RF
ammeter placed at D will read zero amps. How can one amp
be "flowing" out of the top of the coil while zero amps
is "flowing" into the bottom of the coil. That is standing
wave current and it is NOT flowing. It is just standing still
as explained by Hecht.

> These vary together in time according to cos(wt). It
> is not possible to measure the "wrong kind" of current by mistake,
> because there is only one kind.

Sorry, you are wrong about that. A look at the equations while
varying 'x' proves your statement is wrong. Please reference what
Hecht said about those equations in another one of my postings.

You have already admitted that there is more than one kind of
current, e.g. DC Vs RF. It's time to admit that standing wave
current and traveling wave current have different equations and
therefore are different "kinds" of current.

Ian, you know nothing is "EXACTLY" the same. All you can say is that
the two models give acceptably similar results within a certain range
of accuracy.

To paraphrase Roger Whittaker: "'EXACTLY' is for Children Spinning
Daydreams".

> This is the test case that I'm trying to make you apply, to check that
> with a lumped-inductance load, your antenna theory predicts the correct
> behaviour, namely no phase shift in the current through a lumped
> inductance.

:-) That's like proving there's no loss in a lossless transmission
line, Ian. Please send me a 100 uH lumped inductance and I will
run some tests on it and report back to you. What do you want to
bet the lumped circuit model will be wrong?

Some people have a problem with their model trying to dictate reality.
You seem to have fallen into that trap. Allow me to raise my voice.

THERE IS NO SUCH THING IN REALITY AS A LUMPED INDUCTANCE!!!!

The lumped circuit model is an approximation to reality. It has
been patched numerous times as situations came up that it could
not handle. Sometimes it works and sometimes it doesn't work.
Since the distributed network model is a superset of the lumped
circuit model, if there is ever any disagreement between the two
models, the distributed network model wins every time.

The test is not whether the distributed network model yields the
same results as the lumped circuit model. The test is whether
the lumped circuit model yields the same results as the
distributed network mode. That's what the argument is all about.
The distributed network model is the GOLD standard. The lumped
circuit model is just a pale approximation to reality.

> There's no problem with the distributed circuit model. There's no
> problem with the lumped circuit model as a subset of that. All the
> problems are with your incorrect application of those models.

That may be true, but we will never know until you (and others)
recognize the difference between standing wave current and

traveling wave current as explained in my other posting. But
in case you missed it, here is a one wavelength dipole fed 1/4
WL from the right end. ///// is a 90 degree loading coil.

------A------B-/////-D-------------fp-------------

The current at B is measured by an RF ammeter at one amp. The
current at D is measured by a similar RF ammeter at zero amps.
I can provide an EZNEC model if you like. How does your lumped
circuit model explain those measured results?

Source record: 61795

I am not here to pester about own company - I do NOT work for this but just to share experience:
For antenna remoting, etc RF-over-fiberoptic we found www.miteq.com is the best, somehwhat EXPENSIVE but tech specs are best in the world (noise, gain flatness, etc). As you know fiberoptic is the ONLY solution for LOSSLESS & SAFE transmitting RF over a long distance e.g. from antennas, on ship/aircraft, etc because first unlike Coax cable fiber doesn't suffer from excessive loss (you can have a 10-kilometer link no problem!), second it's hard to intercept (if you break fiber it iwll be notices, while Coax cable can be tapped in illegally), third it's immensely interference-immune, etc, etc. though mor eexpensive.

That we found perfcect for Antenna remoting when facilities cannot be built near each antenna (antenna array), also for spying/military application fiber is safer than coax cble, and finally on aircrafts, etc you would prefer fiberoptic due to its immunity to interference (life-safety issues).
So www.miteq.com I found by clicking on "components & assemblies" (NOT satellite comm)-->the clicked "fiberoptic products", they even posted datasheets and brochures there (maybe too much info!)

Ian, GM3SEK wrote:
'There are several methods of finding current distribution."

"I may be a fool, but I`n not the fool to be pitied because I disagreed with Terman. On page 893 of the 1955 edition of "Electronic and Radio Engineering" Terman writes:
"An antenna can therefore be regarded as a resonant system with distributed constants. As a result, the impedance of an antenna behaves in much the same manner as does the impedance of a transmission line (see Sec. 4-7)."

This is not news to many thread participants. Fig. 4-7 on page 96 shows an open-circuited transmission line. At the open circuit there is maximum voltage and zero current. Except for radiation and loss to heat, the typical standing-wave antenna would behave much the same as this ideal transmission line.

Not only does Terman give voltage and current diagrams, he gives a phase diagram. It shows that whenever the voltage or current crosses the zero axis (changes sign) the phase angle changes abruptly by 180-degrees. Phase is unchanging between these inflection points. This agrees with what Cecil has said all along in this discussion.

Best regards, Richard Harrison, KB5WZI

Dave wrote:

> I was taught that there is a 90 degree phase shift in an inductor.

Dave, there is a phase shift between applied voltage and maximum
current. That should not be confused with phase shift or phase
difference in current at both ends of the inductor.

,
> in a loading coil there must be less than 90 degree phase shift because
> the top portion of the antenna still has a small, ~3 to 5 degree, phase
> shift required to achieve resonance. So, does the inductance have a 90
> degree phase shift or an approximate 85+ degree phase shift.

No.

What happens in an antenna is voltage and current are out-of-phase by
some amount. This by definition means the antenna is reactive.

The loading coil's primary function is to shift voltage in relationship
to current, and compensate the relationship between voltage and current
so they are back in phase.

If the loading coil is physically large and has a good amount of
displacement current flowing radially to space and objects around the
antenna compared to through current, the coil would have a noticable
difference in current at the bottom terminal and top terminal. The
current also would also not be in phase when compared at each end.

> Voltage and current are in phase at the base and 90 degrees out of phase
> at the tip, at resonance, conclusion: less than 90 degree phase shift in
> the inductor. PLEASE EXPLAIN this physics anomaly!

Again, you are comparing electrical degrees of the antenna with degrees
phase shift between voltage and current in a circuit containing only a
pure inductor.

Degrees of antenna only deals with the length. It is a way of
expressing length in terms of wavelength, with 360 degrees being a full
wavelength.

Degrees of phase angle in an antenna or any load is really just a
comparison between voltage and current. It is not related to electrical
degrees.

Mixing those two very different things up is a source of great
confusion. If we have a 10 degree tall antenna we really don't need an
inductor that behaves like it is a 80 degree long antenna section to
resonate the system, and the system is not "90-degree resonant". It is

simply resonant. The antenna is 10 degrees long, and the coil is whatever it needs to be to bring voltage back in phase with current.

Consider this. If I have a coil in series with a resistor and measure the input voltage as a reference point, the current at BOTH ends of the coil will lag voltage by a certain amount. If the coil has low capacitive reactance to the outside world compared to the load resistance, current at each end of the coil will be essentially equal. Phase shift in current at each end will be very low.

It's only when the coil becomes physically large and has appreciable capacitive reactance to the outside world compared to the load impedance that it starts to show significant transmission line effects.

Every bit of this is not difficult to understand if we really understand how an antenna behaves and how a coil behaves. The only source of wonderment and argument seems to come from people who want to make the inductor behave differently in an antenna than it behaves in other systems.

It really isn't complicated at all. The very first post in this 900 plus post long thread explained it quite well, and it's been explained dozens of more times along the way. There is no reason to assign special properties to an inductor and make it behave differently in an antenna than it does in other systems.

Hi Yuri,

This was YOUR self-appointed mission. If it doesn't count for much,
or it has no relevancy, then say so and by all means drop it. This
revisiting of old battleground cemeteries is stodgy tourism and I
prefer Buenos Aires. Seeing Evita's tomb in the Recolleta is far more
interesting than watching the grave robbing here.

Which is certainly the case for a 75m bugcatcher coil.

The 75m bugcatcher coil certainly behaves differently mounted
one foot above a GMC pickup ground plane than it behaves in
free space. The question is: which is more common? A GMC pickup
or free space?

> There is no reason to assign
> special properties to an inductor and make it behave differently in an

There is no reason to assume an inductor behaves differently
above a GMC truck ground plane than it behaves in free space???
Tom, would you please describe the free space that exists inside
your head?

That's because the EH antenna and the CFA antenna are based on a
religion or faith, not on science.

No matter what facts multiple independent sources submit, those who
have faith will ignore the facts.

Kraus agrees. Yet W7EL used that unchanging phase to measure the
delay through a loading coil. What's wrong with that picture?

Some people, who no doubt have recognized their technical errors,
simply refuse to discuss the technical subjects. Ian, OTOH, seems
open to discussing those topics so please don't be too hard on him.

I'm a little confused here. Fiberoptic cables don't carry RF, they only
transmit light. What I read in the advertising is a "bandwidth" of upto
atleast 11Ghz. This is a data rate not a RF energy transmission capacity.
Fiberoptic cable is made of "glass" which is nonconductive to RF energy.
Can you expand on the subject.

> An honest person deserves respect whether he is right or wrong.

In accordance with my goal of being honest, here is some ammunition
for the other side of the argument. In Dr. Corum's IEEE paper he
said regarding the Z0 of a loading coil:

"It is worth noting that, for a helical anisotropic wave guide,
the effective characteristic impedance is not merely a function
of the geometrical configuration of the conductors (as it would
be for lossless TEM coaxial cables and twin-lead transmission
lines), but it is ALSO A FUNCTION OF THE EXCITATION FREQUENCY."

I have been assuming that the Z0 of a loading coil didn't change
much with frequency. Both Dr. Corum and EZNEC seem to disagree
with that assumption. So, as is my practice, I am using the
scientific method to adjust my concepts about that subject.

I hope this proves that I am only interested in the technical
facts which have not been proven one way or another as of
this posting.

Hi Marco

Yes but its more of use in a commercial/military than amateur radio environment.

I remember that certain cellular site installs I was involved in ran fiber from a the "main" RF TX/RX device to a remote location. The remote location simply had a broadband amplifier for the separate TX and RX. This was used in an underground railway station going out to maybe 3-4 locations. It was more cost effective doing it this way than by long coax runs at 900/1800MHz.

It will be a cost/benefit tradeoff of whatever RF/SMOF/RF interface device you have to purchase vs the cost of coax vs fiber.

This is something an amateur radio person isnt likely to do for his/her hobby. I also doubt whether it will be commercially viable for amateur radio manufacturers to include fiber interfacing.

OBTW you can tap/intercept optical fibre .

Cheers Bob W5/VK2YQA

The AC6LA website, formerly at www.qsl.net/ac6la, has been moved to:

http://www.ac6la.com/

This is a new domain name and may not yet be registered with all DNS
servers around the world. If the above link does not work, try:

http://www3.qth.com/~ac6lacom

The site contains antenna modeling software and other programs,
including:

MultiNEC - Run Antenna Modeling Programs on AutoPilot - $39
EZPlots - Plot EZNEC Frequency Sweep Data - $19
XLZIZL - Picture the Rest of Your Antenna System - Free
MakeGIF - Make a GIF / JPEG / PNG File from a Clipboard Copy - Free
TLDetails - Transmission Line Program with Animated Charts - Free
MoxGen - Moxon Rectangle Generator - Free

TLDetails and MoxGen are self-contained, the others require that you
have Excel 97 or later already installed.

Huh?
Listen person, it's easy: RF modulates laser at Tx, then at Rx light is demodulated into RF.
Problem is few companies are able to offers specs Miteq offers i.e. gain ;lfatness/distortion, noise, etc. to [preserve original RF signal and 11GHz is not really a limit, they mentioned 18GHz can be built on individual basis (probably costs $18,000 heheheh)

My experience has been that J poles can be fairly fiddely things to really
get right.
By right I mean SWR nearly 1:1 right in the middle of the band. However if
you are not so concerned with 'rightness' they can be a quick cheap way to
get on the air and I have nothing against that. I doubt if putting the
antenna up in the attic help much more than having it in the room near your
position. I have one I travel with made up like a pole lamp(remember these
from the 50s,60s).

Could be too short, Phasing section may be too long. Maybe both. Feedpoint
is probably in the wrong place. Balun couldnt hurt. Add about 10 inches of
coax to the feedline and check SWR again if it changes significantly you
need the balun. Not something fun to play with in the attic.

>> (RESONANT
>> radiator)
>
> The current distribution would not be the same as a half wave, becuase
> the antenna is not 1/2 wave long.
>
Well, is 180 degrees half wavelength or not? Is the current maximum at the feedpoint (center) and zero at the end, or not? The current distribution is not the same, but is exhibiting properties of resonant half wave dipole with current max at the center and zero at the tips. The shape is not the smooth continuous cosine curve as in straight dipole, but affected by the loading coils (drops) in their place (subject of disagreement).

>> Can we describe "pieces" or segments of the radiator as having
>> proportional
>> amount of degrees corresponding to their physical length, when excited
>> with

>
> Yes. It works fine for length. It does NOT work for loading inductors,
> it does not work for short antennas which have anything form a uniform
> distribution to triangular distribution, or any mix between including
> curves of various slopes.
>
Why not? What happens to cosine current distribution curve when we insert the loading element (inductance, coil, loading stub, resistance) in the radiator? What formula applies to get the uniform or triangular distribution? Can you show some mathematics?
So we have resonant standing wave element, that has current max at the feedpoint and zero at the tip, which gives us 90 degree (or 180 with dipole) or quarter wave distribution from the base to the tip. (reality) We can express the straight pieces of radiator in degrees, but not the coiled up piece that the wave has to go through?
The "uniform" and "triangular" distribution was used for approximation or simplification of showing the current distribution in short loaded radiators, while they are in reality segments of the cosine curve belonging to length of the straight portions of the radiator. EZNEC shows that, when you magnify the curve you can see there are no uniforms or triangles but a cosine curve.

> A 30 degree tall antenna with base loading simply has power factor
> correction at the base, provided the inductor is not a significant
> fraction of a wavelength long. It is a 30 degree base loaded radiator,
> not a 90 degree antenna. And the inductor is not 60 degrees long.
>
We are not talking here about base loaded radiator. No detours please.
So how many electrical degrees has the quarter wave resonant radiator that
is loaded with loading coil (or stub) about 2/3 way up and is say 30 deg.
physical "length" to make it resonant?

I think it is significant, not as much in "crummy" mobile vertical, as in antenna systems with loaded, shortened elements.
I saw significant improvement in performance when replacing loading stubs in say KLM 3 el. 80m Yagi with coils. Performance and pattern improved significantly.
If you stick wrong values in modeling program, the error will get only magnified.
That's why this "bothers" me.
I trust what W9UCW measured, and I want to do it myself, just to put the heated subject to rest with proper conclusions.

Yuri

Not if you are in the business of spying! <grin> It takes a machine that can penetrate or couple to the fiber without damaging its throughput (much). I mean given that fiber splicing uses a pretty expensive machine itself I doubt am eavesdropping device would be much harder to manufacture... Your next big expense is to sort through the reams of data that pass through the link!

Do you see it as being viable for amateur radio hobbyists or was your post for general technical interest only? Perhaps I am missing some possibilities here..

Cheers Bob

Cec wrote, "How does one amp at the top and zero amps at the bottom
grab you?
Please see my other postings."

It grabs me that what you wrote in your other postings about
capacitance to the outside world, " I didn't say there was no
capacitance to the outside world. I said
such is a secondary effect, not a primary effect, and for the sake
of the present argument, can be ignored as secondary effects often
are ignored," is all wet. And I still say that your other postings
before that were saying you believed that there was NO capacitance to
the outside world. It was the message they sent to me, loud and clear.

Given any volume, say a volume containing a Texas Bugcatcher coil and
the air inside and immediately around it, if you push more electrons in
than come out _for_ANY_abritrarily_short_time_period_, you have changed
the net charge in that volume; if you pull out more electrons than go
in, you have changed the net charge in that volume. If the current at
the top and bottom, the only two conductors crossing the boundary of
that volume, is different, that represents flow of charge into (and out
of, in a cyclic fashion) that volume. I don't know what to call that
except capacitance to the outside world. Yes, it's _distributed_
capacitance. But the key point is that it is THE reason--the WHOLE
reason--for the difference in current between the top and the bottom,
NOT a "secondary effect."

In fact, when YOU say that the coil "behaves differently" in different
external environments, you are AFFIRMING it as an important effect, for
surely the presence or absence of some American gas guzzler (or is it
Diesel guzzler?) strongly affects the capacitance to the outside world,
and does not significantly affect internal capacitances (which in any
event, being contained entirely within that volume, do NOTHING for
storing net charge within the volume, because for those internal
capacitances to store charge, what goes in one end comes immediately
out the other end which is still inside the same volume and thus there
is not any net change in charge within the volume). But the "other
end" of capacitance to the gas guzzler or whatever is OUTSIDE the
volume of the coil, thus EXACTLY accounting for the difference in
current at the two leads going to the coil. -- I suppose they covered
all that in a sophomore EE circuits class, but I wouldn't know. I
suppose they also might have covered how a pure lumped model using only
i(t)=C*dv(t)/dt and v(t)=L*di(t)/dt, with no time delay elements, can
mimic lossless transmission line behaviour to any arbitrary degree of
accuracy you want, but perhaps they don't try to hit you with that
concept till later. I wouldn't know that, either...I just know it's

true.

I suppose it's a bit too much to ask all at once, but I do wish you could see that just because the specific value of the capacitance is different in different environments, it does not mean that I need a different model. The coil does not behave in some fundamentally different way. I only need to adjust the value of that capacitance within the model--or if you will, the parameters of the transmission-line-like behaviour, though other models may work as well in practical antenna analysis. The model stays the same; the parameters in the model change. When I change the value of a resistor, my model of a resistor doesn't change. It's still fundamentally v(t)=R*i(t). Only the value used for R changes. On a grander scale, when I include the parasitic effects of a real inductOR, I have more things to account for in the model than just inductANCE. Some of them are affected significantly by the environment in which I place the inductor. And even small changes in the values can have a profound effect on the overall system behaviour. That's especially true in a system operated near resonance where the Q is extremely high, such as a system in which there is only a standing wave.

My only wish is that these musings will be useful to the lurkers trying to actually learn something, if there still happen to be any around.

Cheers,
Tom

Some good points there Irv!
7. Is very interesting though. I'm an amateur astronomer as well as a ham
and I'm frequently amused, or saddened, by some of the extreme efforts
to "save" the "Big Bang" theory.
One recent one had negative mass matter, a cosmic repulsion force which
has never been observed and cold dark invisible matter all brought in.
Of course there are WIMPS MACHOS and a period of inflation at many times
the speed of light involved too.
To me that makes the "Big Bang" a very suspect theory!!

And that IS the position of many of the "establishment" cosmologists!
These problems are not just on the science "fringe" unfortunately.
A couple of brave souls recently proposed the simple expedient of very
slighty modifing the inverse square law of gravity at vast distances.
It seems to explain many problems of current theories, but it was
"jumped on" from a great height by scientists who don't ever seem to
have heard of Occam's razor.

Regards Cliff wright.

BTW I have a bet with several of my old colleagues at Auckland
university that LIGO won't detect any "gravitational waves"
So far it has been about 3 years and I haven't had to pay out.

I have to admit that at one time I too thought a viable antenna could me
made from lumped values of inductance and capacitance. I was about 12 or 13
at the time. I am also thinking my analogy with the bicycle rim antenna may
not be so far off. LOL

Hi Yuri,

This is a most ambiguous "bothering" in that you haven't put any
quantification to what the "error" leads to. No one can possibly
expect perfection, and ï¿½20% is possibly the best accuracy most hams
can expect in measurement. We have all already identified that the
"error" stemmed from an inappropriate application of lumped inductance
in the place of a helix in modeling.

This begs the question: "What's all the fuss over? What's to be
proven? and How do we know when it has BEEN proven?"

Hi Bob,

Having done it often, I can say it is far, far simpler than that. It
is obtained through the evanescent mode and optical couplers just like
RF couplers work on the exactly the same principle. You simply abrade
the surfaces of two conjoined lengths of fiber optic; mate them like
snakes along their length; and wah-lah as the French would say.

No. This is not charging a capacitor or a battery. Energy stored in an antenna system is in constant motion. Power delivered by the transmitter is neadly the same as that used by the load, (the antenna), plus that consumed by losses.

Power is simply the in-phase volts times amps. It can have any impedance which is the ratio of in-phase volts to amps. Z in the general case can include reactance plus resistance and can give the apparent power. It is the ratio of volts to amps without regard to phase.

The coil which has a great difference between the current at its ends most likely simply has different impedances at its ends. The power is nearly the same at both ends of the coil but the voltage to current ratios are different.

Varying impredance along the RF path is a product of the interference between the incident and reflected waves. A standing-wave antenna typically has an open-circuit at its end or ends. The RF has no other option but to be returned
toward the sender and make standing waves. The large number of possible incident and reflected wave combinatioms makes it very likely that the current at opposite ends of a coil inserted in the antenna system will be unequal.

It`s the power in and out of a coil in an antenna system that`s likely to be nearly equal at both ends.

Best regards, Richard Harrison, KB5WZI

Try a twin-bowtie antenna with a screen behind it. (They're intended for
indoor use, so the weather outside may eat it up.)

Any complex antenna -- something beyond a loop or bow-tie antenna -- will
discriminate against ghosts. Depending on where the transmitter is, all
your
signals may be ghosts. That is, you're receiving all your signals by
reflections
off SOMETHING and you need to pick the cleanest one, as another poster said.
This sort of "picking" is best attempted with a big, fancy UHF antenna..

Good luck.

NO!

Reality is not on trial here. We are examining your model which is attempting to describe reality. In a test case where the loading is DEFINED to be lumped inductance only, agreement with the lumped-circuit model must be mathematically EXACT.

If one model is a true subset of the other, then as we come closer and closer to the idealized test case, all the extra terms in the bigger model will tend to zero leaving only the subset model. In the limit, the agreement is indeed exact.

(For example, to take up your earlier mis-statement, circuit theory for DC is a true subset of circuit theory for AC/RF. Set "w" (omega) to zero and you're left with only the DC relationships. But there is no discontinuity - as w gets smaller and smaller there is no sudden jump to a whole new theory. When w is exactly zero, we expect exact mathematical agreement with DC theory... and of course we get it.)

We do not expect any real-life loading coil to behave exactly like a lumped inductance, so we cannot physically construct a perfect test case. But we can envisage a perfect test case in order to test the model; and for that, we are entitled to demand exact results.

I'm sorry, but all this is Scientific Method 101. Most people don't need to understand this stuff in detail; though if they do, most people can also appreciate the compelling logic of it.

You have put yourself in a position where you do need to understand scientific logic in some detail, and follow the rules that logic lays down... but you don't.

>> This is the test case that I'm trying to make you apply, to check

>You seem to have fallen into that trap. Allow me to raise my voice.
>
>THERE IS NO SUCH THING IN REALITY AS A LUMPED INDUCTANCE!!!!
>

No, of course there isn't. It is either an approximation or - as in this case - a simplified situation that we can use to check whether theories make sense.

Remember, it is your theory that we're trying to test. The challenge is for you to show that your particular application of the distributed circuit model works correctly.

In a test case where the loading coil comes closer and closer to behaving like a lumped circuit, your model must do the same as all successful distributed models do. All the complications must drop away, giving closer and closer agreement to the behaviour of an antenna loaded by pure inductance only. In the limit where the loading is pure lumped inductance, the agreement must be mathematically EXACT.

I am sure this can be done using a standing wave analysis for a coil-loaded antenna. I am equally sure that you have not achieved that.

Hi Yuri,

This must be a convention that is particular to only a very few Hams.
The FCC database describes AM antennas in both electrical and physical
height as follows.

WGOP 80.00ï¿½ tall 125.2 meters tall 540 kHz
WWCS 63.50ï¿½ tall 98.8 meters tall 540 kHz
WFTD 79.00ï¿½ tall 64.0 meters tall 1080 kHz
KYMN 118.60ï¿½ tall 92.3 meters tall 1080 kHz
WWLV 90.00ï¿½ tall 47.2 meters tall 1620 kHz
WTAW 204.00ï¿½ tall 106.7 meters tall 1620 kHz

There may be some discrepancy, but it certainly looks like antenna
specification is by the electrical equivalent of the physical height
(and whatever l/d fudging) and with only one happening to be 90ï¿½.

Further, given most references (for professionals) is aimed at a
common specification that is largely driven by this agency, it would
seem odd to step out of this expectation to change to calling all
antennas 90ï¿½ simply because they resonate.

Hi Yuri,

This is thin ice. If you are treading along the 1:1 replacement of
coil (wire-length/phase/Vf/whatever) for missing radiator length; then
Cecil is prepared to prove it to within ï¿½59% error.

We could call it Cecil's 1.59:0.41 replacement rule - guaranteed to
prove just about anything, and to whiten your teeth.

No. ..."

OK, I'm going to repeat it once more:

If you shove more electrons into ANY volume than you remove, you have changed the charge within that volume. I do NOT care WHAT is in that volume. Current is the rate that charge is flowing past a point on a conductor. If the only way I have of getting charge into and out of a particular volume is through two wires, then the difference in current at every instant in time represents the time rate of change of charge within that volume. That is true INDEPENDENT of whether it is in an antenna, and it is INDEPENDENT of what's inside that volume.

In fact, energy around an antenna is stored in electric and magnetic fields. These are inexorably linked to inductance along the conductors composing the antenna, and capacitance from these conductors to themselves and to any counterpoise or ground plane which may be part of the antenna--anything where electric field lines terminate. The charge per unit length along an antenna wire, be it resonant or not, be it a "standing wave" or a "travelling wave" antenna, varies with time. If it did not, then the current would necessarily be identical along the whole wire all the time.

This all gets back to very basic definitions of charge, and current as the rate of flow of charge. It's all consistent with Maxwell, Gauss, Faraday, etc. and with waves both standing and travelling, and with "impredances" and all the rest.

It's just amazing to me that some of you are fighting so hard against the very thing which has a chance of unifying your "wave" model with the realities of the electric and magnetic fields, and the associated capacitance and inductance along the antenna--indeed, along the wire itself, and not just along the coil.

Without capacitance, there can be NO difference in current anywhere along the wire, because there is simply no place to put the charge implied by differing currents at differing locations. With capacitance and inductance, everything works just as it's supposed to--just as it

DOES--and a properly developed wave theory will analyze it just fine,
if that's your cup of tea.

Cheers,
Tom

Yuri Blanarovich wrote:
> >
> So what is it then you claiming being equal.

In a loading coil with very small distributed capaciatnce to the outside world compared to termination impedance, current has to be equal. Phase shift in current at each end has to be nearly zero.

This is true for ANY antenna length or loading coil location.

This is what everyone was saying.

> No gang wars intended, just trying to underline that there are two major
> supporting "camps" claiming that the current has to be equal, or is
> appreciably different.

One group is saying the distributed capacitance of the inductor to the outside world controls the distribution, another group appears to be saying it is a function of electrical degrees the coil makes up.

I agree with the majority of people posting in these threads. It is the capacitance from the coil to the outside world that controls current distribution in the inductor and produces and phase difference in CURRENT at each end. If you look at Reg, Ian, Roy, all the Toms, Gene, Richard Clark, and on and on we are all saying that same thing.

Richard Harrison, Yuri, and Cecil seem to argue against that, but that is how ANY inductor behaves. It can be proven to behave the way most people are trying to explain.

The coil does NOT represent the "missing degrees". It does NOT have to have current taper (as a matter of fact a good indictor and antenna design won't show any significant current taper).

> > Right. Although the distributed capacitance can change the shape.
> >
> It can change the amplitude, but not the shape of the current distribution

> and zero at the tips and follows cosine function.

The current distribution in an antenna is primarily a function of displacement currents caused by capacitance to the outside world and series impedance. If I have a short small diameter whip of uniform cross section, it has triangular distribution.

If I sufficiently end-load the very same antenna with no change in length, the current distribution becomes close to uniform. The thinner the elenment and larger the end loading, the more uniform the current.

This is why radiation resistance is someplace around FOUR times greater
in an end-loaded antenna when compared to a base loaded antenna of the
same height. Radiation resistance is tied to ampere-feet, and
ampere-feet is larger with end loading rather than base loading.

> > What "good book"? It would help to see the context.
> >
> Say ARRL Antenna Book, 20th edition, page 16-7, Fig 10

That does not say 90 degrees. It says 15 degrees.

> If you stick the coil at the base in series with radiator and bring it to
> resonance (zero reactance at the frequency of interest) what "degree
> resonant" will than radiator become, if not 90? ("Measured" from the feed
> point, through the coil and then straight radiator.)

It is resonant. It is 15 degrees tall.

It is NOT 90 degree resonant.

Degrees of height is a distance measurement, not an electrical
parameter. If someone is using it to describe resonance thay are
misusing the term.

I can have a 180 degree long resonant dipole.

I can have a 20 degree long resoannt dipole.

I cannot have a 180 degree resonant dipole that is 20 degrees long. I
cannot have a 15 degree tall vertical that is 180 degree resonant, or
90 degree resonant. That argues against itself.

> Well, is 180 degrees half wavelength or not?

Yes, 180 degrees is 1/2 wave.

>Is the current maximum at the
> feedpoint (center) and zero at the end, or not?

Yes.

>The current distribution is
> not the same, but is exhibiting properties of resonant half wave dipole with

So what? The degrees are a measure of physical length. A 20 degree long
coil loaded dipole is a 20 degree long resonant dipole. It is not a 180
degree resonant antenna.

> >> Can we describe "pieces" or segments of the radiator as having

> distribution? Can you show some mathematics?

This has all been explained over and over again. You can also see it in
any engineering book. ON4UN's book initially had it wrong, but it is
corrected now.

> So we have resonant standing wave element, that has current max at the
> feedpoint and zero at the tip, which gives us 90 degree (or 180 with dipole)
> or quarter wave distribution from the base to the tip. (reality)

No, it does not. 90 degrees when used with antennas is a measure of
distance as it relates to frequency. You can't have a 15 degree long
antenna that is "180 degree resonant", and the current distribution
depends on distributed capacitance and series impedance.

We can
> express the straight pieces of radiator in degrees, but not the coiled up
> piece that the wave has to go through?

Right. You cannot build a "60 degree coil to make my 30 degree antenna
90 degrees long".

Think about it. If the coil was 60 degrees long, you could move it
anywhere in the antenna and it would be resonant at the same frequency!

> The "uniform" and "triangular" distribution was used for approximation or
> simplification of showing the current distribution in short loaded
> radiators, while they are in reality segments of the cosine curve belonging
> to length of the straight portions of the radiator. EZNEC shows that, when
> you magnify the curve you can see there are no uniforms or triangles but a
> cosine curve.

Oh, we are picking nits now. In this case we have to get every
engineering book to say "it is such a small portion of a curve it looks
straight" instead of using triangular or uniform.

After all current might be 1.0001 amperes at one point and 1.0000
amperes ten feet away, so I guess that is actually not uniform if we
pick the nits enough.

The cosine shape is not true as a rule, however. That shape depends on
distributed capacitance being uniform.

> We are not talking here about base loaded radiator. No detours please.

If your theory does not cover base, center , and top loading it is incomplete, If it does not treat a coil as a coil no matter how it is used or set limits, it is incomplete.

Base loaded, center loaded. It doesn't matter.

> So how many electrical degrees has the quarter wave resonant radiator that
> is loaded with loading coil (or stub) about 2/3 way up and is say 30 deg.
> physical "length" to make it resonant?

That's already been explained. If it is 30 degrees tall, it is a resonant 30-degree tall radiator.

It is not a "90 degree resonant 30 degree tall radiator with a 60 degree coil".

The FCC data cited does not include the reduced velocity of propagation along the radiator -- which means that an FCC "90 degree" radiator is not resonant, it has some inductive reactance. A network is used at the radiator feedpoint to transform the complex impedance there to properly match the transmission line.

That "90 degree" radiator would need to be shortened by several percent in order to be self-resonant. Kraus (3rd Ed, p 182) shows a feedpoint Z of 73 + j42.5 ohms for a thin-wire, linear dipole that is a physical 1/2-wavelength, and that self-resonance occurs at a length a few percent shorter, when the radiation resistance drops to about 65 ohms.

An unloaded 1/4-wave MW broadcast monopole working against the typical broadcast radial ground system has about 1/2 the impedance that Kraus shows for a dipole in free space.

I think we are striving to improve our accuracy and reflection of reality in modeling antennas.
We know that efficiency is proportional to the area under the current curve along the radiator. The "fatter" the curve, the better. This has been confirmed by the experimental measurements by varying position of the loading coil along the radiator and use of top hats.
If the modeling program starts with wrong assumption (as we have seen using lumped inductance) and one uses multiple elements, like in vertical arrays or Yagis, then the results get skewed and we get wrong "recipe" for the antenna design.
The biggest benefit would be in properly optimizing antenna design for the best rejection, F/B, cleanest pattern, which is more critical than just optimizing for max gain. Especially loaded arrays for low bands would benefit most.
One could get good indication by comparing say 3 el loaded Yagi design with lumped inductance vs. loading stubs or solenoid model.
Unfortunately, or fortunately, I am not retired, nor making living from the RF stuff and my time is limited to be working full time on this. My interest is to maximize the station and antenna design for contesting so I can try to cream some records.
So far, it looks to me that this exercise is worthwhile if we can improve the accuracy of modeling and our understanding of the phenomena.
Looks like lots of antennas would be damaged by the Midwest tornados, the ugly WX is heading our way.

He's right, but to answer your question, you most likely can't. It's my experience that even though these programs use the same extension, (sch,pcb) they are not in the same format. It's not like the extension .TXT which most anything can read these are propitiatory. If these were high end cad programs there might me translators available but not these lower level programs.

> model must be mathematically EXACT.

The distributed network model *does agree EXACTLY* since the
forward current phasor and reflected current phasor add up to
the same magnitude and phase at both ends of the coil. The
forward current is the same magnitude and phase at both ends
of the coil and the reflected current is the same magnitude
and phase at both ends of the coil. So their sums are trivially
identical at both ends of the coil. Since I'm sure you know that
already, your posting seems to me to be a diversion. What you
say is true, but is already trivial common knowledge.

And the agreement is indeed exact. Both models agree up to the point
where the lumped-circuit model starts to fail.

Tom, K7ITM wrote:
"OK. I`m going to repeat it once more."

It is still irrelevant.

The question is:
Does an antenna have a different current at the two ends of an inserted coil?

Anyone interested in antennas should have access to Kraus, 3rd edition, "Antennas". On page 824 is Figure 23-21. Item (a) is a dipole with traps (only 2 terminals) for 2-frequency operation, 1st and 2nd resonances are the purpose of the traps. At F2, current outboard of the traps is practically zero.

At F1, the impedance of the traps still make impedance bumps but the current outboard of the trap ends, though substatially different from that inboard, is enough to allow the dipole to resonate.

At F1 and F2, current at both ends of the coils are substantially different. You probably would put them in a box with only 2 terminals. Pity the fool who argues with Kraus!

Best regards, Richard Harrison, KB5WZI

That is a false statement and is at the root of the misconceptions.
Standing wave current does not have to be equal. I have shown how
current at the bottom of the coil can be zero while the current
at the top of the coil is one amp. Do you think the coil is sucking
that one amp sideways from somewhere else through its distributed
capacitance? There's no magic involved, just simple, easy to
understand, distributed network theory. The current at the top
and bottom of a coil depends upon where it is placed in the
standing wave environment. Standing wave current doesn't flow.
It is the underlying forward current and reflected current that
is doing the flowing. Such is obvious from the equations.

Hecht, in "Optics", has the best description of standing waves
that I have ever read. He says: "[Equation (7.30)] is the equation
for a STANDING or STATIONARY WAVE. Its profile does not move
through space. ... [Its phase] doesn't rotate at all, and the
resultant wave it represents doesn't progress through space -
it's a standing wave."

Translating into RF language. Func(kx)*Func(wt) is the equation
for a STANDING or STATIONARY WAVE, i.e. the standing wave is
stationary. Its magnitude does not move through the wire. Its
phase doesn't rotate at all, and the resultant standing wave
it represents doesn't progress through a wire or through a
coil - it's a standing wave.

Until everyone takes time to understand the nature of standing
waves, people will keep making the same tired mistake over and
over.

I may have said that a pure lumped inductance has no capacitance
to the outside world and that is true by definition. Perhaps that
is what you are remembering. Anyone would be crazy to assert that
a real world coil has no capacitance to the outside world. What I
said is that capacitance to the outside world is often a secondary
effect compared to the primary effect of superposing forward and
reflected currents.

> Given any volume, say a volume containing a Texas Bugcatcher coil and
> the air inside and immediately around it, if you push more electrons in
> than come out _for_ANY_abritrarily_short_time_period_, you have changed
> the net charge in that volume; if you pull out more electrons than go
> in, you have changed the net charge in that volume.

But that is not happening. Standing wave current doesn't flow. It just
stands there. How many times do I have to repeat the following.

Assume the forward current is one amp and the reflected current is one
amp. The standing wave current is the phasor sum of those two currents.

One amp of forward current is flowing into the coil and one amp of
forward current is flowing out of the coil. There is ZERO net storage
of charge associated with the forward current.

One amp of reflected current is flowing into the coil and one amp
of reflected current is flowing out of the coil. There is ZERO net
storage of charge associated with the reflected current.

Since these two currents are the only currents, there is ZERO net
storage of charge in the coil. The magnitude of the standing wave
current is irrelevant.

The forward current at the bottom of the coil is one amp at zero deg.
The reflected current at the bottom of the coil is one amp at 180 deg.
Their phasor sum, the standing wave current, is zero.

The forward current at the top of the coil is 0.5 amp at -90 deg.
The reflected current at the top of the coil is 0.5 amp at -90 deg.
Their phasor sum, the standing wave current, is 1.0 amp at -90 deg.

There's no net storage of charge in the coil, zero amps at the
bottom of the coil, and one amp at the top. That proves that standing

wave current doesn't flow, exactly as its equation says it doesn't flow, exactly as Hecht, in "Optics", says a standing wave "doesn't move through space".

The rest of your posting is irrelevant since it just repeats the same old misconception that standing wave current flows.

That's fine, no argument there. But do you agree that there are towers of X height in meters and when "naked" having Y electrical degrees, loaded with top hat of size S, not changing the physical height, but adding Z degrees. So the top hat adds some degrees to the tower.
Is it such ham radio crime to say that coil can do that too, if it is inserted within the radiator?
We use imaginary lumped inductor to understand coils better, but we can not use electrical degrees to 'splain the behavior of coiled antenna wire?
I think we are progressing into antenna modeling and design and I see nothing wrong with using degrees to describe electrical properties (resonance) of the loaded radiator.

73 Yuri, K3BU

actually
WWLV 90.00° tall 47.2 meters tall 1620 kHz

should show closer to 92 deg. and assuming that they use fatter tower, even more.

Consider a 1/4WL open-circuit stub. The impedance at the open
is very high and the current is zero.

The impedance at the mouth of the stub is very low and the
current is at a maximum.

Exactly the same thing happens with a coil at the self-resonant
frequency.

The standing wave current at each end of a coil installed in
a standing wave antenna depends upon its position in the
antenna. To paraphrase Hecht, standing wave current "doesn't
progress through a wire - it's a standing wave."

> changed the charge within that volume.

That is true but having zero standing wave amps at one end
of a coil and one standing wave amp at the other end doesn't
mean the charge is changing.

If the forward current is the same magnitude at both ends
of the coil, there's no change in charge.

If the reflected current is the same magnitude at both
ends of the coil there's no change in charge.

The standing wave current is the sum of those two phasors.
That sum is what is fooling you. Please pay attention to
Hecht, in "Optics".

The standing wave current profile does not move through
the wire just as the standing wave light profile does
not move through space.

Standing wave current doesn't progress through a wire just
as standing wave light doesn't progress through space.

1. If the magnitude of the forward current is the same at
both ends of the coil, there is no net storage of charge.

2. If the magnitude of the reflected current is the same at
both ends of the coil, there is no net storage of charge.

These conditions satisfies K7ITM's requirements. But he
is being fooled by the sum of the two above currents
which is meaningless to net charge storage.

Statements 1 and 2, above, already prove there is no net
storage of charge. Looking at the standing wave current
is meaningless after that technical fact.

To all and sundry.

You can't locate a loading coil at the top of a short antenna because it requires infinite inductance.

Before it gets to the top it resonates with its self-capacitance, becomes a parallel tuned circuit, and isolates itself from the antenna. The antenna then reverts to an unloaded rod.

The 'mechanism' is modelled in program LOADCOIL, which alows the loading coil to slide up and down the antenna to find maximum radiating efficiency.

There is enough information available to further calculate the angles of the bottom section, the coil. and the top section if you are prepared to find the time and think about it. But I can assure you angles take no part in the internal calculations of the program except perhaps in calculating efficiency. They are just a distraction.

Just enter diameter of bottom section, length and diameter of the coil, and diameter of the top section and slide the coil up and down to see what happens with constant overall height at a given frequency. As a free gift you also get the number of turns on the coil. Its been some time since I used the program myself. It might even tell you the wire gauge.

Download program LOADCOIL in a few seconds from website below and run immediately.

Hi there, Cec,

You wrote,
"If the forward current is the same magnitude at both ends

If the reflected current is the same magnitude at both
ends of the coil there's no change in charge."

Dunno why you keep reverting back to magnitudes, but I'm talking about current as a function of time, and have been consistently through this whole thing. Until you get that straight, there's no point in your even taking part in this. "Cyclical variation in charge (contained within a volume)" means that on average the charge stays constant, but it does not mean that it's constant over some arbitratily short but finite length of time.

Without the capacitance, without the ability to store charge, a transmission line, an antenna wire, a loading coil, all of them--would not have the ability to cause delay. Freespace, without a non-zero permittivity (capacitance), would allow infinite speed of light. But all these things DO have capacitance, and they DO have speed-of-propagation at the speed of light or slower.

Cheers,
Tom

If it's a solution to the wave equation it's o.k., Cecil, but
Hecht is still not using the case where there is a phase difference
between the two waves. If it isn't in the original equation it
won't be in the final version since they're just two ways of
saying the same thing. That's fine because it's the wrong
equation anyway for what you want, which involves impedances

and length, which you probably don't want to deal with because
you're probably under the impression they're just virtual and
not real, and so not worthy of inclusion in your theory.

There is no "helically modeled inductance" in Corum's work. They specifically state that there is none. Instead, they use a substitute, which Reg does, too, and develop their theory from there. Has it ever occurred to you, Cecil, that just as lumped circuit analysis may not be appropriate for everything due to its underlying assumptions, that circuit theory may fail because you can't always reduce the electrical world to current, voltage and length? When are you going to consider field theory in your analysis, Cecil? It might come in handy in any attempt to understand something as complex as a three dimensional coil.

Hecht was talking about two opposing waves of the same phase and
amplitude interfering with each other. You can't guarantee, in a real
antenna,
that the two waves do have the same phase and magnitude.

I assume you are meaning that the RMS current at one physical point
must not equal the RMS current at some other point.

> I have shown how

(snip)

Of course that is what is happening. It is what happens in any
transmission line like device. There is a standing voltage wave,
also, and that produces displacement current through any capacitance,
just as the antenna does.

Aren't you claiming that the coil has transmission line like
properties, in that it takes time for a wave to pass through it?

Any such device needs two mechanisms for storing energy, one magnetic
(inductive) and one electrical (capacitive). Even free space has
both. If you eliminate either mechanism (or make one of them
insignificant, as would happen to the capacitance if the inductor
approaches zero size), you lose the transmission line like properties
as the dominant mechanism.

There is no "net" charge storage on a capacitor in an AC environment, either, Cecil, but you can still get current to go through it. I wouldn't argue with Tom too much if I were you, Cecil, because without the facts he's pointed out in regards to charge, your inchoate theorizing wouldn't mean anything at all.

> place.

If the common-mode current is entering the line directly from a coax shield or from one of the conductors of a "balanced" transmission line, a good choke may well render the impedance so high as to inhibit the common mode current. It will not, however, remove an INDUCED current that is being picked up in the near field of a driven antenna element, though it may change, as you say, the pattern of induced standing waves.

So, while a single choke balun may be sufficient in the former case, in the latter, it may well be necessary, as you say, to place one every quarter wave along the portion of the feedline in the antenna's near field.

On a more practical note, if feedline radiation is not actually damaging some important aspect of an antenna's pattern, it is often sufficient to choke off common mode currents AT THE TUNER so as to keep them out of the equipment, where they tend to cause problems, especially with today's solid state gear. If the pattern is a problem, then more drastic means may be needed. The most common common-mode current problems occur in unbalanced designs like "Windom" antennas (a true Windom uses a radiating single wire feedline). Most mast-mounted beam and vertical antennas will induce very little current on coax that is routed straight down the mast.

Mobil installations can be a problem, though, since the car body is part of the antenna system and can induce strong currents on the coax outer braid. As well, the outer braid may show a fairly low impedance at the feedpoint. An isolator can alleviate this considerably.

It IS very suspect. The trouble is, nobody has an iota of a clue what to replace it with. And this will probably remain the case until we have some solid quantum theory of gravity to work with.

Yes...very often the replacement "laws of nature" turn out to approximate very closely to the ones we had before. After all, a "law of nature" is really just a VERY persistent (and often mathematical) observation about nature.

Thanks, Tom.

In fact, let's get back to something very basic about antennas.

Acceleration of CHARGE results in electromagnetic RADIATION.

RADIATION impinging on a receiving antenna (and on anything else that freely transports charge) causes acceleration of CHARGE within that antenna.

So when we are talking about antennas, it is very appropriate to be talking about charge, and exactly what happens to it to move it around and to accelerate it as a function of time, everywhere in the structure.

A voltage applied to the feedpoint terminals of an antenna causes CHARGE to be put into motion. Accumulation of CHARGE along the conductors--the distribution of charge as a function of time and space--in turn results in electric fields in the vicinity of the antenna. Motion of charge results in magnetic fields in the vicinity of the antenna. Capacitance and inductance are manifestations of the electric and magnetic fields, respectively. Taken as a whole, the motion of charge and the resulting electric and magnetic fields give rise to waves: the waves, too, are manifestations of the electric and magnetic fields. ALL of these are consistent with each other, and to a very good approximation agree with the descriptions worked out by Faraday, Gauss, Maxwell and all many years ago. (We don't need quantum theory to be talking about performance of an 80 meter mobile antenna!)

Please, let's keep it straight that the motion of charge is FUNDAMENTAL to all this analysis, and everything else will fall out very nicely from an accurate accounting of the motion of charge within the system. It is NOT irrelevant at all; it is at the very heart of the operation of ALL antenna systems.

Cheers,
Tom

The current reported by EZNEC is RMS current, Tom. What happens
within a cycle is irrelevant to this discussion.

We are not and never have been discussing variations within a
cycle. There's just no point. We have been discussing RMS values
of currents. Your attempt to again divert the issue is noted. We
are talking about net charge spread out over many steady-state
cycles. That net charge is always zero no matter what the RMS
value of the standing wave current at the ends of the coil.

> Without the capacitance, without the ability to store charge, a

Please tell us something we don't already know.

It has become apparent that the discussion is not about coils at
all. It is about the nature of standing waves whether existing
in a transmission line, a standing wave antenna wire, or a coil.

Tom Donaly wrote:
> If it's a solution to the wave equation it's o.k., Cecil, but
> Hecht is still not using the case where there is a phase difference
> between the two waves.

Yes, he is, Tom. The phase *disappears* when you add the two
traveling waves. That you don't recognize that fact of physics
is the source of your misconception. The forward and reflected
wave phasors are rotating in opposite directions at the same
angular velocity. That makes their sum a constant phase value
for half the cycle and the opposite constant phase value for
the other half of the cycle.

I and Richard Harrison have already explained that a number of
times quoting Kraus and Terman.

Here are a number of problems. I(f) is forward current and
I(r) is reflected current. Please everybody, perform the
following phasor additions where I(f)+I(r) is the *standing
wave current*:

I(f) I(r) I(f)+I(r)

1 amp at 0 deg 1 amp at 0 deg _____

1 amp at -30 deg 1 amp at +30 deg _____

1 amp at -60 deg 1 amp at +60 deg _____

1 amp at -90 deg 1 amp at +90 deg _____

1 amp at -120 deg 1 amp at +120 deg _____

1 amp at -150 deg 1 amp at +150 deg _____

1 amp at -180 deg 1 amp at +180 deg _____

If you guys will take pen to paper and fill in those blanks
you will uncover the misconception that has haunted this
newsgroup for many weeks. If you need help with the math,
feel free to ask for help.

That's a fair question, Tom. The answer is just as soon as someone comes up with an example for which the distributed network model fails. We have plenty of examples where the lumped circuit model fails but not one example yet that the distributed network model won't handle.

> antenna, that the two waves do have the same phase and magnitude.

:-) Hecht was talking about two coherent EM waves traveling in
opposite directions. We are talking about two coherent EM waves
traveling in opposite directions. There is a small traveling
wave component but it doesn't affect the standing wave. It is
what is left over from the standing wave.

This discussion has not been about coils. We need to discuss
an unterminated lossless transmission line and then move on
to 1/2 wavelength thin-wire standing wave antennas.

Yes, the RMS value of the standing wave current at the bottom of
the coil doesn't have to bear any relationship to the RMS value
of the standing wave current at the top of the coil.

> Aren't you claiming that the coil has transmission line like properties,
> in that it takes time for a wave to pass through it?

Yes

> Any such device needs two mechanisms for storing energy, one magnetic
> (inductive) and one electrical (capacitive). Even free space has both.
> If you eliminate either mechanism (or make one of them insignificant, as
> would happen to the capacitance if the inductor approaches zero size),
> you lose the transmission line like properties as the dominant mechanism.

There is no net charge carried over from cycle to cycle. There is no
net storage of charge even if the steady-state RMS value of the standing
wave current is zero at one end of the coil and 2 amps at the other end.

The problem here is not how a coil works. The problem is how standing
waves work. Forget the coil. Start with a lossless unterminated
transmission line and then step up to a 1/2 wavelength thin wire dipole.

It is obvious that a number of people just don't understand the nature
of a standing wave that doesn't move through a wire along with its
phasor that doesn't rotate relative to the source.

Agreed that current is charge in motion. Accumulation of charge,
however, is a job for an accumulator, another name for a storage
battery. These have little to do with the possibility of an antenna coil
having currents through the coil from opposite directions creating
unequal totals at the ends of the coil.

I don`t know if this Tom is picking a fight to gain attention before
going to Dayton but his postings have the right fragarance.

These cellular extenders (that I am familiar with) were a simple way to
put a broadband "antenna" at a remote location and have it behave as if it
was connected by coax. One sector antenna of a cell site could be
allocated to the remote location and all the control and system interface
wasn't complicated in any way -- except for accounting for the coverage area
(which was usually a RF hole needing coverage).
With the amount of equipment required to do it right (modulate the RF onto
the fiber and demodulate it and amplify it back to the required level), it
would be just as easy for a ham to simply put the rig at the remote location
and send control and audio up the fiber -- if he really wanted the
advantages of fiber.
There are fiber boxes that do this for a fraction of the cost of the
"RF" type --- they have audio and digital interfaces. If you can do it on
the Internet, fiber is simple as well.

What misconception? That all current in a standing wave has the same
phase, rather than one of two possible phases?

Of course. no one is talking about the red herring of charge stored
over a whole cycle. Everyone (except, possibly you) is talking about
charge stored and recovered twice per cycle.

> There is no net storage of charge even if the steady-state RMS value
> of the standing wave current is zero at one end of the coil
> and 2 amps at the other end.

And no one but you brings up "net storage". We are all talking about
ordinary capacitive charge storage within a cycle. And there are two
equal and opposite half cycles of that. If there is Ac voltage and
capacitance to the universe, there is charge storage, twice within

every cycle, one positive and one negative.

> The problem here is not how a coil works. The problem is how standing
> waves work.

Standing waves have AC voltage swing. That applied to capacitance causes real charge storage and retrieval. Just as it does with traveling waves. How could the standing AC voltage not charge and discharge, charge the other direction and discharge every cycle, the capacitance between the conductor and the universe?

> Forget the coil. Start with a lossless unterminated
> transmission line and then step up to a 1/2 wavelength thin wire dipole.

The capacitance in a lossless transmission line is between the two conductors. For the 1/2 wavelength thin wire dipole, the capacitance is to the surroundings. But the charge stored and dumped into that capacitance twice a cycle is very similar, except that in the case of the antenna, some energy leaves in the form of radiation.

> It is obvious that a number of people just don't understand the nature
> of a standing wave that doesn't move through a wire along with its
> phasor that doesn't rotate relative to the source.

It is obvious to me that you are one of them. Every point on a line carrying a standing wave (except the node points) has AC voltage on it, and AC current through it. The amplitude and phase of those voltages and currents can be described as a phasor, with respect to some reference phase of the same frequency. As you move along the line, the amplitude changes and when you pass through a node the phase reverses. So the phasor does not rotate with position change, except for a step change of 180 degrees at nodes, rather than smooth rotation with respect to position.

For a traveling wave, every point on the line has an AC voltage on it, and an AC current passing through it. The amplitude is constant along the line, but the phasor rotates as you move along the line (the phase is linearly dependent on position). But at any single point on the line, a non rotating phasor describes the amplitude and phase with respect to a reference phase of the same frequency.

Richard Clark wrote:
"This must be a convention that is particular to only a very few hams.
The FCC database describes AM antennas in both electrical degrees and
physical height as follows."

It is the convention to describe AM broadcast towers in electrical
degrees. Harold Ennes reprints an RCA resistance chart for heights
between 50 and 200 degrees in "AM-FM Broadcast Maintenance".

Formula given is:
Height in electrical degrees = Height in feet X frequency in kc X 1.016
X 10 to the minus 6 power.

Example Towers:
50-degrees self-supporting: R=7. jx=-j100
50-degrees guyed mast: R=8, jx=-j222
90-degrees self-supporting: R=40, jx=+j35
90-degrees guyed mast: R=36, jx=j0
200-degrees self-supporting: R=23, jx=-j50
200-degrees guyed mast: R=80, jx=-400

There are values of R and X for 16 different heights. If you are
interested, look at the book.

Best regards, Richard Harrison, KB5WZI

The misconception is not yours, John. W7EL used that current to
try to measure the phase shift through a coil and so did W8JI
who came up with an unbelievable 3 nS.

Of course, *everyone* except you and Tom Donaly are talking about
charge stored over a whole cycle. That's the entire base of their
arguments. The unbalance in the *RMS* current at the bottom of the
coil and the *RMS* current at the top of the coil is what the entire
discussion is all about.

The currents measured by W8JI and W7EL were *RMS* currents. The
currents reported by EZNEC are *RMS* currents.

> And no one but you brings up "net storage". We are all talking about
> ordinary capacitive charge storage within a cycle.

If so, that is completely irrelevant to the discussion since
W8JI and W7EL are using *RMS* currents for their measurements
and EZNEC is reporting *RMS* currents.

Let me summarize it for you. W8JI and W7EL apparently think
that the RMS current value of zero at the bottom of the coil
Vs the RMS current value of one amp at the top of the coil
means energy is being sucked into the coil from some external
source.

How about assisting in a tutorial on standing waves rather
than diverting and obfuscating the issues?

Cecil, if you don't put any phase information in your
original formula it won't be there when you say the
same thing some other way. But if you
do put it in there, then it has to affect both formulas.
If it disappears, you've done something wrong. If you and
Harrison can't figure out how to extract phase information
from a standing wave you should return your diplomas to
wherever you got them from.
73,
Tom Donaly, KA6RUH
(P.S. Let me give you a hint: first you have to find
out what phase means in a standing wave on a transmission
line. You probably already think you know, though, so I
don't expect you to bother much about it.)

There's a potential for ambiguity here, and that ambiguity has been used a number of times in this thread to cause confusion. So let me try to clarify things.

All phasors "rotate", in that every one contains an implicit term e^jwt. That term describes a rotation of the complex phasor quantity at the rotational frequency w (omega), but no change in amplitude. If a quantity doesn't include this implicit term, it's not a phasor, by definition. We can look at any phasor quantity in a system and compare the phase of its rotation with the phase of a reference, and from this assign a phase angle to it. In steady state, the phase angle doesn't change with time -- it's the phase difference between the w - rotating phasor and the w - rotating reference. Phasors of different rotational rates (that is, of different frequencies) can't be combined in the same analysis, unless the implicit term is made explicit, in which case they're no longer phasors.

The use of "rotation" in John's posting is talking about a change of phase with physical position. This usage has been confused with the time rotation of the phasor which comes from the implicit e^jwt term. I'd prefer to use the term "phase", which doesn't change with time in a steady state system, directly rather than "rotation" to describe a change in phase with position.

With that convention, we see that the phase of a pure traveling wave changes linearly with position. But when we sum forward and reverse

traveling waves together to get a total current (or voltage), the phase of the total current (or voltage) is no longer a linear function of position. In the special case of an open or short circuited transmission line, where the forward and reverse traveling waves are equal in amplitude, the phase doesn't change with position at all (except for a periodic reversal in current and voltage direction, which can be interpreted as a 180 degree phase change). But the phasor representing total voltage or current (which Cecil refers to as "standing wave current") at any point, which is the sum of two phasors representing forward and reverse traveling waves, does indeed rotate at w (omega) radians/second rate, just like its constituent phasors. The constant phase with position (of an open or shorted line) simply means that if you froze time at some instant and looked at the angles of the rotating phasors representing the total current at each point along the line, you'd find them all to be at the same angle. They're all rotating.

This isn't revolutionary or controversial -- you can find phasors discussed in any elementary circuit analysis text.[*] And it's not difficult to do the summation of forward and reverse traveling waves to see the result, but if you'd like to see how someone else did it, one of the clearest discussions I've found is in Chipman's _Transmission Lines_, a Schaum's Outline book.

[*] You have to be a little careful, though. In most introductions to phasors, the author introduces the e^jwt term early on, and quickly drops it from the phasor notation as is customary. So it's easy to forget it's there. But remembering that it is there is vital to understanding this topic, and to keep from being misled by misdirection which takes advantage of confusion and abbreviated notation.

Well, I guess it's o.k. for you to believe that when a wave travels down
a transmission line it always ends up in phase with where it started.
That simplifies things for your theory. It doesn't make for a very
good transmission line, though.

I don't read their responses that way. I read their responses as
saying that the current leaving or entering an end of an inductor
includes a capacitive component and an inductive component. The
capacitive current branches out of the coil to the surrounding space,
and is what allows a measured difference in the currents passing
through its two ends. The path through the wire to the other end is
not the only path for current.

Hello Jim I built a 910mhz coax antenna using 6 - 1/2 wave elements, 1/4 wave on bottom and the top. I used 3/8" copper hardline instead of coax i had to tried to adjust for a faster .88 VP but found using the same length as required for RG58 worked just as well. Initally i did not put the antenna up because at ground level it did not work very well on recieve, i was going to throw it out but desided to put it up anyway. It really made a big difference once it was in the air @ 25', it works much better than a Sinclair commercial omni i had been using,

Absolutely true. Cecil complains that people won't engage in a technical discussion with him. Many have tried, and all we get in response is evasion, misquotes, diversion, and brushing off of any evidence contrary to his preconceived notions.

Anyone who wants to know what I said or what I think should read what I've posted. If it's not clear, ask. But don't trust Cecil to tell you.

What is unique about the new HDTV antennas? We just picked up a new HDTV with a tuner and was advised to pickup a simple HDTV antenna to pick up the local digital broadcast. Any magic to these other the high gain claims on the boxes?

Dick;

There is absolutely nothing unique about a so called HDTV antenna. I would get a good quality antenna though. Stations are currently transmitting at reduced power to save a few dollars until they have to goto high power.

> If it disappears, you've done something wrong.

There is no phase information in standing wave phase, Tom.
I can't find it, Gene fuller can't find it, Eugene Hecht
can't find it, and James Clerk Maxwell can't find it.

Any and all phase information in the standing wave phase
disappears during superposing.

Let me give you another example. Assume that we superpose
one amp of DC current flowing in one direction and one
amp of DC current flowing in the other direction. What
does the superposed amplitude tell us about the amplitudes
of the superposed currents? Nothing, except they were
equal.

It is an approximation, Tom, like a lossless line. For real world dipoles, the voltage and current decay by about 10% between the forward wave and the arrival of the reflected wave. Kraus and Terman both use that approximation in their examples.

We aren't saying anything about the traveling wave part of the waves. The discussion is about the standing wave portion of the wave which, by definition, requires equal magnitudes.

Yes, when I said standing wave current phase doesn't rotate, I meant
with respect to the source current phase. At any instant in time,
the phase of the standing wave current is unchanging up and down
the line.

Assume the standing wave current all up and down the dipole is of
constant phase with no variation with 'x'. Roy, you used that
current to try to measure the delay through a coil. How did you
plan to measure that delay with a signal known to be the same
phase not only at both ends of the coil but all up and down
the antenna?

If that's what you think and you can find someone to discuss
energy exchange within a cycle, be my guest. As far as I know,
Tom Donaly introduced the subject as a diversion.

> I don't read their responses that way.

I couldn't believe it either but after years of arguing with them,
it is apparent that many of the gurus here on r.r.a.a are simply
ignorant of the nature of standing waves.

I really expected them to shout, "April Fool, we have been pulling
your leg!" But, sad to say, they are serious about standing wave
current "flowing" into the bottom of the coil and out the top.
They apparently haven't read "Optics", by Hecht where he says:
"E(x,t) = 2Eo*sin(kx)*cos(wt) This is the equation for a standing
wave, as opposed to a traveling wave. Its profile does not move
through space. ... [The standing wave] phasor doesn't rotate at
all, and the resultant wave it represents doesn't progress through
space - its a standing wave." If standing waves of light don't move
through space, standing waves of RF don't move through a wire.

>I read their responses as saying
> that the current leaving or entering an end of an inductor includes a
> capacitive component and an inductive component. The capacitive current
> branches out of the coil to the surrounding space, and is what allows a
> measured difference in the currents passing through its two ends.

That is a secondary effect. The primary effect is the phasor addition
of the forward current and reflected current which you provided.

Compared to zero amps of standing wave current when the forward current
phasor and the reflected current phasor are 180 degrees out of phase,
just how much effect can capacitance have?

Tom, do you or do you not believe that standing wave current flows
into the bottom of the coil and out the top? It's a simple yes/no
question. You have earlier stated that "current is current" and
that, in spite of the different equations for for the two currents,
standing wave current moves like traveling wave current in spite
of what Hecht had to say in "Optics".

"E(x,t) = 2*Eo*sin(kx)*cos(wt) This is the equation for a STANDING
or STATIONARY WAVE, as opposed to a traveling wave. Its profile does
not move through space; it is clearly not of the form Func(x +/- vt).
... [Standing wave phase] doesn't rotate at all, and the resultant
wave it represents doesn't progress through space - its a standing
wave."

If standing waves of light don't move through space, standing waves
of RF don't move through wires.

Time to stop the ad hominem attacks and address this technical issue.

Roy, I'll tell you the same thing I told W8JI. It's time to stop
the ad hominem attacks and discuss the technical issues.

You tried to use standing wave current, containing no phase, to
measure the delay through a coil. You have said previously that
standing wave current flows just like traveling wave current.
You said that in spite of what Hecht says in "Optics".

Hecht had to say in "Optics":

"E(x,t) = 2*Eo*sin(kx)*cos(wt) This is the equation for a STANDING
or STATIONARY WAVE, as opposed to a traveling wave. Its profile does
not move through space; it is clearly not of the form Func(x +/- vt).
... [Standing wave phase] doesn't rotate at all, and the resultant
wave it represents doesn't progress through space - its a standing
wave."

If standing wave light doesn't move through space, then standing wave
RF doesn't move through a wire. Do you disagree with Hecht?

Your idea of phase is to compare amplitudes at two separate
places on the same wave and noting the time difference in
behavior. You're right, you get the same "phase" if you
do that to a standing wave in a lossles medium. You're not
right, however, in thinking that the phase difference between
two waves travelling in different directions down a transmission
line can never be known. But as I wrote before, that isn't what
you should be after. You should want to know the Beta*l of
the coil on your antenna so you'll know its electrical length.
And you can know it if it is true that you can model a coil
as a simple transmission line. That's a big if, but it's something
you should have thought of before you shot off your mouth.

The discussion is no longer about coils. It's clear that a
lot of posters don't understand the nature of standing waves.
If they don't understand standing waves in a transmission
line or on a wire, they cannot possibly understand standing
waves on a coil.

A standing wave voltage passes exactly as much (AC RMS) current
through a capacitance as a traveling wave voltage does. If there is
voltage at the ends of the coil, then there is capacitive current
driven by those voltages, regardless of whether the voltage is from a
single traveling wave or the superposition of two of them.

Cecil wrote, "It's time to stop
the ad hominem attacks and discuss the technical issues."

Ready when you are, lad. Suggest you start by establishing just how it is that an antenna wire supports waves. Gauss's theorem and Faraday's law may come in handy. Please don't spare anything.

The reason you need to do this for me to even begin to believe you have any idea what you are talking about is that you have rejected out of hand some very fundamental concepts that I've put numbers on for you. You ask for something, and then you reject the answer but give no valid reason why. I've tried to give you a way to SUPPORT what you are saying, and you can't even recognize that, apparently.

Now YOU go back to the real fundamentals and give it to us straight, with full math treatment. Until you do, as far as I'm concerned, you don't have a leg to stand on. If you can do a credible job starting with Maxwell's equations, I might begin to believe you have some understanding of the subject. And I don't want it parroted from someone else's writing, I want it done from the ground up by you.

If you have some trouble doing that with an antenna wire, just try it with an ideal coaxial TEM line. It's easy there; I've done it out of idle curiosity one evening, and it was quite enlightening to see how nicely it all agreed with what I already knew about propagation along a line.

Lay it on us, Cecil. Start with the fundamentals. And don't be dragging out that tired old travelling-waves/standing-waves stuff till you've established that you actually can even have waves, and just what it is that governs their behaviour.

Cheers,
Tom

Tom Donaly, KA6RUH wrote:
""---first you have to find out what phase means in a standing wave transmission line."

Cecil knows very well what phase means in a transmission line. Terman describes it best for me, but it would be best to have his book with all his diagrams which makes his explanation of how standing waves are established simple indeed.

Terman writes on page 89 of his 1955 edition:
"Transmission line with Open-Circuited Load."
(This is related to the standing-wave antenna which also ends up with an open-circuit load.)
"When the load impedance is infinite, Eq.(4-14)
(This gives the reflection coefficient rho as the vector ratio of the reflected wave to the incident wave at the load) shows that the coefficient of reflecftion will be 1 on an angle of zero. Under these conditions the incident and reflected waves (voltages) will have the same phase. As a result, the voltages of the two waves add arithmetically so that at the load E1 = E2 = EL/2. (Voltage doubles at the open circuit.)

Under these conditions it follows from Eqs. (4-8)
(Eforward/Iforward=Zo) and (4-11)
(Ereflected / Ireflected=-Zo) that the currents of the two waves are equal in magnitude but opposite in phase; they thus add up to zero load current, as must be the case if the load is open-circuited.

Consider now how these two waves behave as the distance l from the load increases. The incident wave advances in phase beta radians per unit length, while the reflected wave lags correspondingly; at the same time magnitudes do not change greatly when the attenuation-constant alpha is small. The vector sum of the voltages of the two waves is less than the arithmetic sum, as illustrated in Fig. 4-3a, for l=lambda/8. This tendency continues until the distance to the load becomes exactly a quarter wavelength, i.e.,until beta l = pi/2. The incident wave has then advanced 90-degrees from its phase position at the load, while the reflected wave has dropped back a similar amount. The line voltage at this point is thus the arithmertic difference of the voltages of the two waves, as shown in Fig. 4-3a, for l=lambda/4 and it will be quite small if the attenuation is small. The resultant voltage will not be zero, however, because some attenuation will always be present, and this causes the incident wave to be larger and the reflected wave to be smaller at the quarter-wave length point than at the load, where the amplitudes are exactly the same."

This is enough of Terman`s desctiption to establish the pattern of SWR.
He describes simply but not too simply. Almost anything anyone would
want to know is in the book. The illustrations are worth thousands of
words.
Anytime I have any doubt about radio, Terman can straighten me out.

Best regards, Richard Harrison, KB5WZI

> a capacitance as a traveling wave voltage does.

But the two waves are different as can be seen from their
equations. A traveling wave transfers net energy along a
transmission line or antenna wire. A standing wave transfers
zero net energy along a transmission line or antenna wire.

From "Fields and Waves in Modern Radio", by Ramo & Whinnery,
2nd edition, page 43: "The total energy in any length of line
a multiple of a quarterwavelength long is constant, merely
interchanging between energy in the electric field of the
voltages and energy in the magnetic field of the currents."

Hecht says it best in "Optics" concerning standing waves:

"The composite disturbance is then:

E = Eo[sin(kx+wt) + sin(kx-wt)]

Applying the identity:

sin A + sin B = 2 sin 1/2(A+B)*cos 1/2(A-B)

yields:

E(x,t) = 2*Eo*sin(kx)*cos(wt)"

"This is the equation for a STANDING or STATIONARY WAVE, as opposed
to a traveling wave. Its profile does not move through space; it is
clearly not of the form Func(x +/- vt)."

[Standing wave phase] "doesn't rotate at all, and the resultant
wave it represents doesn't progress through space - its a standing
wave."

Speaking of "... net transfer of energy, for the pure standing
wave there is none."

:-) Just one more attempt at a logical diversion.

I think we can all assume that EM waves exist and are
capable of propagating along a transmission line, or
antenna wire, or even in free space, e.g. light.

What we cannot assume is that standing waves move
or progress through space (or wire). Eugene Hecht
says they don't.

>but we can not
>use electrical degrees to 'splain the behavior of coiled antenna wire?

I can see how problems could arise going by the length of coil
wire length in degrees only. Lets say you run a coil 1 foot from the
base. Lets say that coil uses 25 turns to tune a particular frequency.
Now, move the coil up 2 ft higher, and see if that same 25 turns will
tune the same frequency. It won't. You will have to add a few more
turns.
So just going by the total mast plus coil wire length in degrees could
vary
all over the map just by changing the position of the coil. As you
raise
the coil, you will have to add more and more of "degrees" of wire to
tune the same frequency. :/
Dunno...There may well be some variation of current from the bottom
vs the top of the coil, but overall, I still view the operation of a
loading
coil as a "lumped" mechanism overall.
Even if you all decide that the current changes, or it doesn't , it
ain't
gonna make a hoot's worth of difference in the design of mobile whips.
I think it's an argument that has no real value to me as far as mobile
whips go. The performance of all the various coil heights, and configs
have been well known for years. Coil current taper or not.
I just don't see the facination with arguing about something that even
if
decided one way or the other, still won't make any difference in the
final
antenna design. Oh well...Continue the tail chasing excercise....
I'm outa this one... One post is all I will waste on this subject..
I couldn't mount my coil much higher if I wanted to... Current taper or
not. :/

Well, Cecil, you've certainly shown your knowledge is weak in
this area. You can improve the general knowledge by being the
first to crack the books.

Cecil, how can you quote Hecht when you don't have the foggiest notion
what he's talking about?
Here's a more general equation for you Cecil:
(A1-A2)*Cos(wt-kx) + 2*A2*Cos(kx+d/2)*Cos(wt+d/2). Do you have
any idea what it should represent? Does it satisfy the wave equation?
Does it represent anything real? Sit and think about it before you
get hysterical.

The nature of standing waves is not a difficult subject. Some
people have a single particular misconception about standing
waves that have lead them to technically incorrect conclusions
about standing wave antennas. In fact, before I brought up the
subject, it appeared they didn't even realize that a mobile
antenna is a standing wave antenna.

Given a lossless, unterminated transmission line, with two black
boxes located at points along the line.

Source----------a-BBox-b-------------c-BBox-d----------open

The current at 'a' is one amp and the current at 'b' is zero

The current at 'c' is zero and the current at 'd' is one amp

What's in the black boxes?

If electrical length is defined as the physical condition where feedpoint reactance is zero (e.g., resonance), then the true electrical length of an AM broadcast radiator on a given frequency is a function of the physical length AND physical width of that radiator. This was proven experimentally, and documented by George Brown of RCA Labs in his paper "Experimentally Determined Impedance Characteristics of Cylindrical Antennas" published in the Proceedings of the I.R.E. in April, 1945. It also has been proven in thousands of independent measurements of AM broadcast radiators ever since.

The curves in Figure 3 of Brown's paper show the feedpoint reactance terms of the base impedance of an unloaded monopole of various lengths and widths, working against a nearly perfect ground plane. Those values cross the zero reactance axis at physical heights ranging from about 80 degrees (for the widest radiator) to about 86 degrees for the most narrow.

Brown calculated height in degrees as (Physical Height in feet x Frequency in kHz) / 2725 . Brown's equation, the one in the Harold Ennes quote above, and the one that the FCC uses in their published data all define only the relationship of the physical length of the radiator to its free-space wavelength in degrees at that frequency.

But clearly these lengths in degrees do not define the self-resonant length of that radiator. The self-resonant length, invariably, will be shorter by several percent. This fact is easily confirmed by simple NEC models, for those who want to probe into George Brown's data.

Tables relating a single value of base impedance as typical for towers of various electrical heights (only) must be read with an understanding of the above realities. For example, Ennes' list shows a tower of 90 electrical degrees to have zero reactance. But Brown's 1945 paper and a great amount of later field experience shows that this is incorrect, for the conventional use of this term.

Yes, it is more general, Tom, but since the subject is standing waves and not traveling waves, it is overly general. Why would you post an equation containing a traveling wave term when the subject is the equation for standing waves?

This is the total equation for the condition where power is being delivered to a load in the presence of standing waves. The first term makes it to the load. The second term doesn't.

The first term is a traveling wave and indeed does contain phase information. There's no argument about whether a traveling wave contains phase information.

The argument is whether the second term, the standing wave term, contains phase information. Gene Fuller says it doesn't, Eugene Hecht says it doesn't, and I'm inclined to agree.

Dick,

Since the vast majority of HDTV channels are on UHF, make sure that you have good UHF performance. If using an outside antenna, and you do other OTA viewing, you might as well get a good one that covers VHF/UHF. I particularly like the Channel Master antennas with boom lengths anywhere from 6 to 10 feet. In most cases there is no such thing as too much signal. Of course, if you are really close to the transmit towers, you can get exactly that. As far as a "simple" antenna...you may find that you have multi-path problems with them. Lots of variables to consider, but none of them have anything in particular to do with HDTV <grin>.

Your best bet is to go to the antennaweb site, plug in your zip code or location and see what antenna they recommend. This site is used by a lot of HDTV enthusiasts.

MK, that is the whole point, that you portray missing or not appreciating.
It might not matter to you if you lose $100, but it might matter to someone
else. Same with loading coil. What you are describing, the effect where the
coil is located, being known, is the result of the phenomena we are trying
to straighten out, explain and apply properly in modeling and design
exercises.

The position of coil within the antenna has significant effect. The worst is at the base, fewer turns required. The best is somewhere about 2/3 up the radiator, more turns required. You stick it on the top, no stinger or hat, you get it almost invisible. With what we are discussing and defending here is the proper understanding of the current flow in the loading coil and its drop across and its effect on the efficiency of the loaded antenna. Efficiency is proportional to the area under the current curve distribution along the radiator. If you properly model the coil as solenoid or loading stub to see the real drop of current across the coil and its effect in various positions along the radiator, the all is clear and is with agreement with practical experience, antenna shootout results, measurements.
As I mentioned numerous times, its effect on design and modeling loaded antenna systems will be even more pronounced, because effect gets magnified when you start adding elements. This is especially important when you try to design super receiving antennas for low bands where F/B and clean pattern is very desirable and is the most critical aspect of antenna design or modeling. It is harder to obtain the max F/B or least rear lobes than to maximize the design for max gain.
It might not matter to you, but I am sure many would benefit from knowing more precisely what is REALLY going on and then use or correct their design methodology.
I think it is fine for you to ignore this and poh-poh it. But I know how huge difference it made in my 160m mobile antenna when I extended the whip to the front bumper with wire.
We are not saying that piece of wire that coil is wound with, has so many electrical degrees. If we carefully consider and understand the phenomena, you would realize that the radiator has same electrical length (say 15 deg) and when you move the coil and ADJUST THE TURNS to bring the antenna back to resonance (90 deg) that coil would "replace, take care of" 75 degrees. The turns have to be adjusted in order to "participate" in the current replacement game. The lesson is, the higher you place the coil on the radiator, the more turns you need to reresonate the radiator, the high current portion of the antenna current distribution curve gets "stretched up", better efficiency (larger area under the overall curve). Then the coil DROPS the current across itself to some lower value, which then continues to drop across the tip and that area, quite smaller adds to the one from the bottom part of the radiator.
This all is supported by reality, except "gurus" who insist that the current is (about) the same across the coil and they make (theoretically) antenna current to be higher across the tip and "more" efficient than it is. Again, you stick 6 of those in the 3 el loaded Yagi design and you get GI-GO.

It is known how profound effect had replacement of loading stubs by coils in the KLM 3 el. 80 m loaded Yagi. Better gain, huge improvement in the F/B and pattern. Has been done and described. And this is just replacing the same inductance value stub with coil, where delta current from stub wires was enough to throw monkey wrench in the Yagi performance. Now consider larger error from the wrong assumption or calculation caused by wrong current magnitudes and distribution.

Again you might not give a hoot about this "trivial" exercise, but if I want to design 4 el loaded quad or Yagi for 80 or 160, it matters a lot.

So it just amazes me that some of the smarter heads resist so much in trying to find out reality and develop better consideration of the effect for design and modeling. No technical answers to Cecil's questions and my "from scratch" thread deteriorated into pink electrons and dead end in electrical degrees.

So far what we have is the reality, few who are trying to legitimize it and few who got off on the wrong foot, in effort to preserve their (wrong) face they cling to it with scientwific "proofs" why it can't be so, when IT IS. When I tried to go step by technical step through the case, the "gurus" are not there. Cases that Cecil showed in EZNEC model and demonstrating that current across the loading coil (not one in the box) in the antenna can have anything from equal to "nothing" at the other end, depending on its position in the standing wave picture. It all jives with our original argument. We spotted the "problem", we dissected it, thanks to fierce flat earthers, and now have better understanding of the phenomena and can use to design better antennas.
I care about antennas, this is the last frontier where we can still improve thing, now with modeling tools. I still operate contests and go for ultimate - beating the all time records, and that's where the edge can be obtained.

Heloooo guys!
Measure, feel, whatever, the frickin' current across the loading coil and then come back and tell the world why it IS different, but IT CAN'T be so, because you said so in the beginning and you just can't admit being wrong. Reality can't be twisted, just like Earth is not going back to flat!
Saying now that is no big deal, not important, will not exonerate the "wrongoes". It is significant not to be ignored. If I was in "their" shoes, I would say: "gee guys, interesting, thanks for bringing it up, explaining it, I guess we were wrong, now we can design better antennas". Stay tuned.....

Thanks again Cecil, Richard and others for putting up with and shedding more and more light on the phenomena. It must go down in history as big as Galileo's fight :-) I am glad that, hopefully, nobody will burn us.

The phase shift in degrees along a transmission line is a very fixed quantity. Regardless of how it is used or what sort of circuit it is in.

The only way to change it is to change line length or frequency.

Reg.

That a self-resonant, unloaded broadcast radiator length is shorter than the 90 degree conventional "electrical length" defined by the FCC is a given. But this reality sometimes is not recognized.

That difference is a difference in the pattern (distribution) of voltage and current along the line, as well as a possible difference in amplitude and phase at any given point. But at any point that is not a node in the standing wave pattern, there will be an ordinary AC voltage or current at some amplitude between double the traveling wave amplitude and zero amplitude, and one of two phases (that switch each time you pass a node).

> A traveling wave transfers net energy along a
> transmission line or antenna wire. A standing wave transfers
> zero net energy along a transmission line or antenna wire.

No argument. But a standing wave still represents storage of energy in the line, as with any resonant structure, and that stored energy shows up as magnetic fields and electric fields along the line. The big difference is that the magnetic fields bob up and down at some areas and the electric fields bob up and down half way in between those areas. At any given moment, there is a fixed total energy in the combination of all the magnetic and electric fields.

In the areas where the electric field is bobbing up and down, there must be capacitive current caused by that variation in electric field.

> From "Fields and Waves in Modern Radio", by Ramo & Whinnery,

Exactly. How can you write this, but deny the capacitive current that delivers this electric field energy twice every cycle to all capacitance feeling this voltage swing?

>
> E(x,t) = 2*Eo*sin(kx)*cos(wt)"

cos(wt) is the AC swing that drives the capacitive current. sin(kx) is the positional variation of that AC voltage along the line. I have absolutely no argument with the expression, only with your understanding of what it says.

>
> "This is the equation for a STANDING or STATIONARY WAVE, as opposed
> to a traveling wave. Its profile does not move through space; it is
> clearly not of the form Func(x +/- vt)."

Profiles do not charge capacitance, instantaneous rate of change of voltage drives current through capacitance. cos(wt) describes a sinusoidal variation of voltage over time (you couldn't have an RMS value of voltage at a point or an RMS value of current past a point, without it.

>
> [Standing wave phase] "doesn't rotate at all, and the resultant

> wave."

I suggest you drop talking about phasors, till you understand what cos(wt).

> Speaking of "... net transfer of energy, for the pure standing
> wave there is none."

But it does represent net storage of energy. The total stored energy is the sum of energies in the two traveling waves over the length. A standing wave does not violate conservation of energy.

Storage that must continuously be swapping back and forth from magnetic field energy to electric field energy. When the energy storage is all electric, that implies charges capacitance.

Don't give up, the light may be just about to come on.

Cecil, I won't try to educate you because it's a waste of time, but
for everyone else, consider that in an antenna, there is
energy going into, and being radiated out of, the antenna in the
form of an electromagnetic wave. Since Cecil says standing waves
can't transfer energy from one place to another (he didn't always
say this) that means that the only way energy can be radiated is
through the traveling wave component of the electromagnetic wave.
You would think that this would be important to him in his search
for a dumbed down theory of reflection mechanics, but evidently
he is more interested in his arguing point concerning Tom R. and
Roy measuring current in a standing wave environment than he is in
reaching an understanding of what he's talking about. No wonder
no one's communicating with him.

No argument, and therefore no need for the "But" in your statement.
I agree with you but it doesn't change a thing about the real
argument.

> Exactly. How can you write this, but deny the capacitive current that
> delivers this electric field energy twice every cycle to all capacitance
> feeling this voltage swing?

I don't deny it - never have - never will. Please stop trying
to set up straw men. The discussion has *NEVER* be about what
happens during one cycle. The current measured by W8JI and W7EL
and reported by EZNEC is RMS current. Instantaneous values are
just another straw man diversion.

> Profiles do not charge capacitance, ...

I'm glad you agree. Profiles are maximum RMS envelope values
and that is what EZNEC reports.

>> [Standing wave phase] "doesn't rotate at all, and the resultant
>> wave it represents doesn't progress through space - its a standing
>> wave."
>
> I suggest you drop talking about phasors, till you understand what cos(wt).

Hecht and I have been a little lose with words while assuming
the readers have a certain knowledge level. For the uninitiated,
When Hecht (or I) say the phasor doesn't rotate at all, we
mean the phasor doesn't rotate at all with respect to the
source phasor. Any initiated person would know that. The phase

of the standing waves doesn't change with respect to the phase
of the source signal. Hecht assumed you would know what he meant
by that statement.

>> Speaking of "... net transfer of energy, for the pure standing
>> wave there is none."
>
> A standing wave does not violate conservation of energy.

Exactly my point! Nothing violates conservation of energy. If
the RMS forward current in the coil is the same magnitude at
both ends and the RMS reflected current in the coil is the
same at both ends, the conservation of energy principle is
satisfied NO MATTER WHAT THE STANDING WAVE CURRENT TURNS
OUT TO BE. What is it about that statement that you don't
understand?

> Storage that must continuously be swapping back and forth from magnetic
> field energy to electric field energy. When the energy storage is all
> electric, that implies charges capacitance.

Again, nobody has ever been discussing what happens within a
partial cycle. Discussion of such is obviously a diversionary
straw man. Feel free to find someone else willing to discuss it.
It is completely irrelevant to this discussion of RMS envelope
values.

(continuing on)

This is the property that allows us to distinguish whether a black box contains a length of transmission line or an approximation of that made of lumped series inductors and shunt capacitors. The approximation will mimic a transmission line, only if the impedances driving and loading it are in a range, and only over some frequency range. The approximation of a transmission line is good, only under some conditions.

Cecil,

You dismissed my honest, straightforward accounting of the charge transport implied directly by the scenarios you set up. In no way was it a "logical diversion." It was very much to the point of explaining just WHY there is in fact a time delay through your bugcatcher coil.

Then you have the unmitigated gaul to say it's time to stop the attacks, and then refuse yourself to get into a serious technical discussion.

Away with you, evil spirit. And be very happy that this is a polite forum.

For instance, EZNEC says a 33 ft. vertical made of #30 wire is
resonant on 7.265 MHz while a one foot diameter pipe is resonant
on 6.9 MHz.

Does the FCC define physical lengths or electrical lengths?

"Cecil Moore"
> Does the FCC define physical lengths or electrical lengths?

They call it an electrical length, but calculate it as the number of free-space electrical degrees contained in the physical length of the radiating structure, at the carrier frequency. So really, FCC "electrical length" is a measure of a physical length, not of an effective electrical length.

The effective electrical length of a MW monople radiator determines its resonant frequencies, and that must include the velocity of propagation along the structure -- which is a function of the height AND width of the radiator (mainly), and the operating frequency.

Richard Clark, KB7QHC

PS
So seeing that "from scratch" is beginning to show why, flea bites,
it's time to add some real entertainment value that befits the
gravitas of this opera:

"Pal-yat-chee"

[H&J]

When we was in the city, we was a-wonderin' where to go.
The sign spelled out "Pagliacci" up in lights above the show.
We thought 'twould be a Western, 'til the stage lit up with light,
And ninety-seven people sung, without a horse in sight!
We couldn't unnerstand 'em 'cause they spoke a furrin tongue,
But we can give you some idear of what we think they sung---

[tenor]

Ridi, Pagliaccio,
Sul tuo amore infranto!

[H&J]

All at once, there's a fat guy in a clown suit.
'Tain't Hallerween, that's for shore!
Then this here feller,
This Punchy-neller,
Begins to beller,
Like we all was deef!

[tenor]

Ah, hahahahahahahaha....

[H&J]

That was Pal-yat-chee, and he sung:

Invest in a tuba, and somethin' or other 'bout Cuba,
He sung about a lady, who weighed two-hunnerd-and-eighty.
When she takes a powder, he just starts chirpin' louder,
An' he don't mean a gol-durned thing, 'cept to stand up there and
sing.
When we listen to Pal-yat-chee, we get itchy and scratchy.
This shore is top corn, so we go an' buy some popcorn.
We hate to go back, but we cain't get our dough back;
Ain't no use complainin', 'cause outside it's a-rainin.

[Slicker chorus]

Seven hours later, we're still in the durned thee-aye-ter,
Takin' turns a-nappin, a-waitin' fer somethin' to happen.
Pal-yat-chee, he ain't worryin',
And the folks on stage are flurryin',
And it sounds like Kat-che-turian's "Sabre Dance".

[to the melody of "Sabre Dance"]

Then ole Pal-yat-chee finds the guy he's seekin' cheek-to-cheekin'
With his wife, he grabs a knife
And stabs the louse who stole his spouse
And then he stabs the lady and him self,
'Tain't very sa-ni-ta-ry.
They all collapse,
But then Pal-yat-chee sets up and he gets up singin'
"I am dyin', I am dyin', I am dyin'", we start cryin'
'Cause to tell the truth, we're dyin', too.

[end "Sabre Dance"]

As the footlights fade out, we see Pal-yat-chee laid out,
But the dagger never caused it: Pal-yat-chee was plumb ex-haus-ted!

[tenor]

Ridi, Pagliaccio,
Sul tuo amore in--

[loud belch]

[vaudeville stinger: da-dut dahhhh da-dut DAT! DAAAAAAAHHH! cymbal crash]

That's true, but compared to the standing waves, it is pretty
small. In fact, when Kraus talks about a 1/2WL thin-wire dipole,
he completely ignores the traveling wave and energy "lost" as
radiation and assumes the forward wave and reflected wave have
the same magnitude. If you want to argue that trivial point, take
it up with Kraus.

Here's what he says: "It is generally assumed that the current
distribution of an infinitesimally thin antenna is sinusoidal,
and that the phase is constaant over a 1/2WL interval, changing
abruptly by 180 degrees between intervals.

That would only be true if the reflected wave was equal in
magnitude to the forward wave, i.e. no loss due to radiation
or I^2*R losses. If Kraus gives us permission to ignore the
traveling wave for purposes of discussion, who are you to
argue?

I have calculated that there is only a 10% drop between forward
voltage or current and the reflected voltage or current arriving
back at the feedpoint for a 1/2WL dipole. For the sake of discussion
of standing waves in standing wave antennas, with an accuracy within
10%, the loss due to radiation can be ignored according to Kraus.
It's akin to ignoring the losses in a transmission line for the sake
of discussion.

> Since Cecil says standing waves
> can't transfer energy from one place to another ...

> through the traveling wave component of the electromagnetic wave.

Yes, that's true and since I have never said otherwise, this
seems to be just another straw man. With an accuracy of about
10%, Kraus gives us permission to ignore the traveling wave
in standing wave antennas for the purposes of discussion.

The biggest clue that you are not arguing in good faith is that
you trimmed out all the technical content and didn't quote
anything I said. This posting of yours is disembodied from
reality so you can demonize me and emote your angry gut feelings.

Responses with no technical content and no quotes are an obvious
attempt to obfuscate - so obfuscate away.

It is possible I misunderstood what you were trying to say but
unless you quote something of technical value, I will have no
idea what my misunderstanding, if any, was all about.

John P. seems to want to discuss instantaneous movement of
energy. Why don't you two keep that discussion going?

The simplest (without a reference phase) would be cos(wt). The
standing wave function contains this term, with a modifier to tell you
how amplitude varies with position. But at any point, cos(wt) times
some amplitude describes the ordinary AC voltage or current swing.

EZNEC must take those within a cycle currents and voltages into
account to come up with the amplitude values. The RMS value is just
the amplitude value for a cycle.

>> Profiles do not charge capacitance, ...

See? We agree on lots of stuff.

>>> [Standing wave phase] "doesn't rotate at all, and the resultant

>>> wave."

At a given point the traveling wave phasor doesn't rotate, either.
Phasor rotation only applies to the phase change over length for a
traveling wave. The phase for standing waves has a discontinuous jump
as you pass through a node, instead of a continuous rotation over
length. I guess one might call that a form of jumpy rotation. Who
doesn't recognize these facts?

You don't add superposed RMS values to get the resultant RMS value.
You have to add instantaneous values over a cycle (so that the

relative phases of the two wave cycles are taken into account), and take the RMS of the resultant cycle. See? We have to get inside an individual cycle to understand what is going on. You cannot just deal with RMS (while cycle amplitude values) and get the same answer. This is why I (and others) keep coming back to what is happening inside a cycle, instead of discussing RMS values, only. One cannot understand either traveling wave mechanisms or the super position to a pair of traveling waves (a standing wave) if you think only in RMS values. They display the result of the process, but hide the way the process produces that result.

>> Storage that must continuously be swapping back and forth from

I have. You may not be, but that is your lack.

> Discussion of such is obviously a diversionary
> straw man. Feel free to find someone else willing to discuss it.
> It is completely irrelevant to this discussion of RMS envelope
> values.

There is no discussion of RMS envelope values. There is just you repeating the same thought, over and over, while the rest of us discuss the mechanisms that produce that resultant envelope.

You obviously understand how a phase measurement is useless to measure phase shift within a half cycle of a purely standing wave process.

I am waiting for you to realize that you can measure the phase shift of each of the traveling waves that superpose in a standing wave process that includes a coil (or any other network) by using only the RMS amplitude envelope, with no reference to phase, in an EZNEC simulation or a real experiment. That was the whole point that began this discussion, wasn't it?

You keep showing how the current into and out of a particular coil does not have the same RMS value. We get it.

Now, measure the phase shift of that coil (for each of the equal amplitude waves traveling through it) without having to change its environment to put it into a pure traveling wave process. And don't use a phase measurement to do it (which you know is impossible). Use the amplitude envelope. You should be able to measure its phase shift to within a degree or so. And you can then see how that phase shift changes (or if it does) when you move the coil to different places in the standing wave system.

The FCC provides BOTH measurements. The correlation is obvious. Any
association between resonance, velocity of propagation, height, width,
etc. and something like our 118.60ï¿½ tall antenna needs a heap more
explaining than resonance, velocity of propagation, height, width,
etc. - but such explaining is a specialty occupation here in this
group.

==================================
Yes. An artificial line of series inductors and shunt capacitors is a
low pass filter. The propagation delay in time is relatively constant
until near the cut-off frequency when it increases rapidly.

At frequencies beyond cut-off it stops working.

A true transmission line doesn't have a cut-off frequency.

I see that Cecil's latest fetish is that EZNEC reports RMS values of voltage and current. Because we know that the voltages and currents are purely sinusoidal, the RMS value and phase angle (also reported by EZNEC) are adequate to define the time waveform. That is, when we know the RMS amplitude and the phase angle, we know the value of the waveform at every instant in time. No additional information is necessary.

303. Question about auto antenna cable and connectors

Newsgroup: rec.radio.amateur.antenna
Date: 2006-04-04 19:17:12 UTC
From: Ronnie <rhughes4-removeme@swbell.net>
Message-ID: <YCzYf.64385$Jd.48901@newssvr25.news.prodigy.net>
Source record: 61645
Cross-posted to: rec.radio.amateur.antenna,rec.radio.amateur.homebrew

Hi,

This is not about ham radio, but rather a general question
about the type of cable and connectors that were found
between the antenna and the AM radio in GM cars in the
60's. I'm trying to locate some technical information about
the cable and a source for the cable and connectors.

I have an old airplane autopilot system that uses tuned circuit
to sense changes in the airplane's attitude and the position of
the control servos. Distributed variable inductances and
variable capacitors combine to establish the resonant
operating frequency of the system. The components are
connected together with specific lengths of cable and the
service manual points out that the lengths are critical because
of the added capacitance of the cable and connectors.

The cable is marked as follows:

"I. T. & T. Federal Cable R.E.C."

It is a shielded cable with a spiral wound center conductor
that looks very much like the antenna cable I remember finding
in GM cars in the 60's. It also has the same type of connectors.
There is a center pin for the center conductor and a metal sleve
that extents back over the cable and makes a connection with the
shield and chassis of the radio. Friction holds the connector in
its mating socket - there are no threads, just a couple of splayed out
areas on the sleve.

I was hoping one of you might be able to point me to a source
of technical information about this cable, such as the capacitance
per unit length, etc. The one piece I have measures about 10.5 pF / foot
or 415 pF / meter, but my measurements may not be all that accurate.

Also, a source where the cable and connectors can be found today
would be appreciated.

Thanks in advance for any help.

Ronnie, N5CSE

> amplitude describes the ordinary AC voltage or current swing.

But please notice that cos(kx+wt) is different from that term.
The only time they are the same is if 'x' = 0. Is 'x' always
equal zero? No. All your equation tells us is that whatever
current it represents, it is always in phase with the reference
source at 'x' = 0. So your equation is too simple to be useful.
Please try again.

> EZNEC must take those within a cycle currents and voltages into account
> to come up with the amplitude values.

"Must" or "does". I have no idea.

> At a given point the traveling wave phasor doesn't rotate, either.

On the contrary - at any given point 'x', the traveling wave
phasor is rotating with respect to the source phasor. That's
what makes it different from a standing wave phasor which
doesn't rotate with respect to the source phasor.

> Phasor rotation only applies to the phase change over length for a
> traveling wave.

No, that's wrong. Take another look at cos(kx+wt). Holding 'x'
at a constant value, the phase keeps on changing. The traveling
wave phasor is rotating with respect to the source. The standing
wave phasor is not rotating with respect to the source, just
as Hecht says speaking of standing waves: "The resultant
phasor is E1 + E2 = E ... Keeping the two [traveling wave]
phasors tip-to-tail and having E1 rotate counterclockwise as
E2 rotates (at the same rate) clockwise, generates E [total] as a
function of 't'. ... It doesn't rotate at all, and the resultant
wave it represents doesn't progress through space - it's a
standing wave."

You really need to get you a copy of Hecht's "Optics". It the
best treatment of standing waves that I have ever seen - also
best at superposition and interference explanations.

> You don't add superposed RMS values to get the resultant RMS value.

Sure you do. Current #1 is an RMS value at angle 1. Current #2
is an RMS value at angle 2. The superposition is:

RMS#1*cos(A1) + RMS#2*cos(A2) = RMS(total)

> There is no discussion of RMS envelope values.

Where have you been? The currents displayed by EZNEC are RMS
envelope values. The antenna currents plotted in Kraus and
Terman are RMS envelope values. The currents measured at the
top and bottom of the coils by W8JI and W7EK are RMS envelope
values.

> I am waiting for you to realize that you can measure the phase shift of
> each of the traveling waves that superpose in a standing wave process
> that includes a coil (or any other network) by using only the RMS
> amplitude envelope, with no reference to phase, in an EZNEC simulation
> or a real experiment. That was the whole point that began this
> discussion, wasn't it?

Yes, I said that months ago but nobody would buy the argument.
Over those months, I have given countless examples proving that
to be true. Everyone just ignored those technical facts as they
have ignored 95% of the technical content of my postings only
to concentrate on the 5% containing feelings or bad humor.

> Now, measure the phase shift of that coil ...

Sorry, the coil is obviously not the problem. Everyone understands
how a coil works. What everyone doesn't understand is how standing
waves in a wire work. That will be my topic of discussion from now
on. But feel free to continue the coil topic with anyone else.

> Grow up Cecil. Everyone sees what you are doing.

Everyone should see that I am trying to discuss technical
issues while the rest of you object to the 5% of my postings
that are bad humor or complaints about how I am being
unfairly treated.

Why do you refuse to discuss technical issues? For
instance, you have avoided responding to my black box
question. Are you afraid everyone will see just
how wrong you are?

Here is it again assuming a lossless transmission line:

Source----------a-BB-b------------c-BB-d----------open

The current measured at 'a' is one amp.
The current measured at 'b' is zero amps.
The current measured at 'c' is zero amps.
The current measured at 'd' is one amp.

What are the possibilities for what could be in the
black boxes?

There could be 90 degrees of transmission line in
each box.

Or there could be 90 degree coils in each box.

Or one box could contain 90 degrees of transmission line
and the other contain 90 degrees of coil.

Ok, I'll bite once more since you have put so much work into
that post.... :/

>MK, that is the whole point, that you portray missing or not appreciating.

Yes. It is quite true. I don't really appreciate the importance of
knowing
if the current tapers across a coil or not. Even if I did, what could I
do about
it? But you can consider this a personal problem...

> It might not matter to you, but I am sure many would benefit from knowing
>more precisely what is REALLY going on and then use or correct their design
>methodology.

How are you going to to fix what is not broke? There is nothing wrong
with the current state of mobile whip design. I don't see how it can be

improved without going to unpractical measures. Deciding whether or
not there is current taper across the coil is not going to help you
improve a mobile antenna one whit.
Now, I'll agree there might be other app's where it could be useful to
be aware of this, but not for mobile whips.

> I think it is fine for you to ignore this and poh-poh it. But I know how
>huge difference it made in my 160m mobile antenna when I extended the whip
>to the front bumper with wire.

No kidding.... I've never heard of adding a longer whip to improve a
mobile antenna. :/ What does coil current taper have to do with this?
I could have told you about adding longer whips way before you even
thought
about current taper. I've never needed current taper technology to
know
that adding a longer top whip to a short mobile antenna will generally
improve
performance.
Have you ever tried Reg's "vertload"? You can play "what if" till the
cows
come home... I often have...

>The lesson is, the higher you place the coil on the
>radiator, the more turns you need to reresonate the radiator, the high
>current portion of the antenna current distribution curve gets "stretched
>up", better efficiency (larger area under the overall curve).

And this lesson is new? Get a grip...I've been aware of this for years.

And I think most others have been too...

>This all is supported by reality, except "gurus" who insist that the current
>is (about) the same across the coil and they make (theoretically) antenna
>current to be higher across the tip and "more" efficient than it is.

You can't fool a field strength meter. It makes no difference whether
one
believes there is a taper or not, the antenna is still going to perform
the
same for a given coil height on a given height mast.

>It is known how profound effect had replacement of loading stubs by coils in
>the KLM 3 el. 80 m loaded Yagi. Better gain, huge improvement in the F/B and
>pattern. Has been done and described. And this is just replacing the same
>inductance value stub with coil, where delta current from stub wires was
>enough to throw monkey wrench in the Yagi performance. Now consider larger
>error from the wrong assumption or calculation caused by wrong current
>magnitudes and distribution.

Not a very good example. Sure, replacing inferior stubs, or whatever
methods
of linear loading are usually going to be improved by changing to coil
loading.
No big surprise. If doing this makes a large improvement in f/b,
pattern, etc,
sounds like it was a poor design from the git go... I still don't
follow how
knowing about current taper is going to help you much here. How will
you
apply this knowledge? Will this "improved coil taper technology"
improve
performance more than 1 db? At this point, I won't be holding my
breath.

>Heloooo guys!
>Measure, feel, whatever, the frickin' current across the loading coil and
>then come back and tell the world why it IS different, but IT CAN'T be so,
>because you said so in the beginning and you just can't admit being wrong.

Dunno...I think you have me confused with someone who really gives a
hoot.
I could care less if you are right or wrong. What I want to know is how
is this
"knowledge" going to improve a mobile whip. ?
I'll grant you that there may well be cases where knowledge of this
could
be useful. Mainly when modeling very complex antennas.
But as far as the basic mobile whip, knowing about current taper across

the coil is not going to help you improve the antenna one bit.
Trying to say that it showed you that you need to add a longer
capacitive

whip to a 160m antenna is silly.
You can run "vertload" and see the appx best place for the coil very quickly. No current taper technology will be used, yet it will be quite accurate for most all uses.
This coil taper effect you have spent months trying to prove may seem very important to you, but to me it's fairly ho-hum..."snore" It's been shown
that the possible errors in modeling are going to be generally small and usually under 1 db in most cases.
There may be something useful to come out of all this, but it ain't going
to be an improvement of mobile antenna design. I think it's safe to say you can take that to the bank. The optimum location of a coil on a short whip is already well known and etched in fairly hard material. Deciding there is current taper across the coil is not going to change this.
MK

Since EZNEC has been mentioned so much lately, it's appropriate to point out that it's able to calculate the current at all points along a helically modeled loading inductor with what I believe to be very good accuracy. And it does it without any use or knowledge of presumed traveling voltage or current waves. It deals only with the total current. Perhaps Cecil would benefit from investigating how this is done.

EZNEC uses NEC-2 for calculations, and the NEC-2 manual is available on line at no cost. A detailed description of its methodology is presented in Part I. For those who want just a general overview of the method (the method of moments) in a more easily understood format, one can be found in the second and later editions of Kraus' _Antennas_. I notice that most newer antenna texts also include a description of the moment method, and it should be available in the web as well.

Thanks for the reference, Roy, I'll take a look at it.

One wonders how EZNEC tells the difference between a
standing wave antenna and a traveling wave antenna
"without any use or knowledge of presumed traveling
voltage or current waves".

I'm willing to bet it doesn't use lumped circuit
theory. :-) I'm also willing to bet that forward
and reflected waves are taken care of in the
equations used by NEC.

You really think so, Cecil?? I saw through it the first time you posted it. As an EZNEC and NEC2 user, I know that not only the current magnitude, but also its phase, is reported. I knew that what you posted about it was incorrect. I don't see Roy's comment as agreeing with you at all, but completely disagreeing. You said that it only gave amplitude information, when in fact it gives phase and amplitude.

Experience, my dear, experience.
If I am capabl;e of writing to you, I don't have to put number on it, how
many letters of alphabet I master.

> What is the error? You also speak of efficiency. What is the
> efficiency?
>
Stick in the EZNEC and find out if you can't sleep without numbers.
Anyone who looks at current distribution curves can see that there is a
difference. No need for lawyers and precise numbers. If only this was the
problem, then I would give you answer to 4 decimal places. You have greater
problem with "gurus" not getting the big picture (or pretending to).

> Very simple questions. Technically based. Selected because they seem

> handle on the situation.
>
I have the handle on it, appreciate the magnitude and with time there will
be some numbers.
Cecil posted files, anyone who is hang up on numbers can get them from the
EZNEC if properly defined, instead of poking needles.
We are having problem with people admitting there could be difference in the
current across loading coils, and here the "problems" is what is the error?

So lets stick to the big problem and fuggettabout detours and nitpicking.

Again, no quote from me. I have no idea to what you are responding
or even if you are responding to something I said today or last year.

I didn't say EZNEC doesn't give phase information. I said there is
no phase information in the phase information that EXNEC gives.
What is it about Gene's posting that you don't understand?

Actually, the problem is more elementary than coils. Everyone
seems to understand coils installed in circuits.

The ignorance seems to be of the nature of the physics involved
in standing waves, whether on a wire or on a coil or in free
space. So I have switched the discussion to where it belongs,
to a discussion of standing waves, with or without coils,
with or without wires.

I offered the following example which the gurus refuse to touch
with a ten foot pole. One wonders why. The transmission line is
lossless and BB is a black box.

Source-------a-BB-b-----------c-BB-d---------open circuit

The current at 'a' is measured at one amp.
The current at 'b' is measured at zero amps.
The current at 'c' is measured at zero amps.
The current at 'd' is measured at one amp.
What's in the black boxes?

Would you believe ZERO responses from the gurus?

319. Antenna RF choke questions

Newsgroup: rec.radio.amateur.antenna
Date: 2006-04-04 22:08:58 UTC
From: AK <nomail@aol.com>
Message-ID: <_7CYf.908089$xm3.833232@attbi_s21>
Source record: 61661

Putting together a new Cushcraft A4S (10,15, 20m) beam.

Cushcraft recommends using an 8-turn, 6-inch diameter RG8U coax cable coil as an RF choke for feeding the driven element. HyGain suggested the same thing for the TH2MK3 antenna I used many years ago -- only using 12 turns of RG8 (with the 6-inch outside diameter), rather than 8 turns. I have a few questions on the best way to do this.

1) Is it fair to assume that the more turns the better?

2) Should the coil be as close to the antenna feedpoint as possible, or is a foot or two of straight coax between the antenna input and the coil OK?

3) Would placing the coax coil around the mast (instead of taping one side of the coil to the mast as suggested) be a bad thing to do?

4) Is there a good website or book that describes the technical tradeoffs of a coax RF choke? (I am sort of wondering if the choke can be skipped. Some time ago, I used a W2AU balun on a multiband dipole. All it did was create TVI when I went on 10 meters. Took the balun out, and the resonant points didn't change. I figured that if there were antenna currents on the coax, they would bring down the resonant frequency without the balun. Since that didn't happen, I figured the balun wasn't helping - - but balun core saturation at 30 MHz (with the KW on) was what was racking up the TVs.)

5) One last question - not having to do with the coax RF choke:
Cushcraft "operating tips" say to not use vinyl tape on SO239 or PL-239 connectors. Why? What problem would the tape cause??

Thanks for any info - AK

Yuri,

Rather than playing like Cecil and making words for others, please post the dates and statements made by people who say current cannot be uneven at each end of a coil.

Show us where that is said with an exact in context quote, don't pull a Cecil and invent something that you expect us to blindly accept as the truth.

It would help if we knew what you were talking about.

Hi Yuri,

So, after all these years, you have more grief than numbers. You
cannot give us the accuracy necessary to resolve this, and you haven't
got a number to call efficiency. The solution has long been offered,
so this must be more a matter of personality than technicality.

>So lets stick to the big problem and fuggettabout detours and nitpicking.

You haven't told us how "big" problem is, and with more tears than
numbers, "big" seems to be an emotional measure. You would get more
traction hiring professional mourners for this wake. At least we
could count them to see how important the corpse was.

To this point there seems to be only one mourner, and a Texas cowboy
spitting in his face and calling it the refreshing dew of early
spring.

> On the contrary - at any given point 'x', the traveling wave
> phasor is rotating with respect to the source phasor.

That is not what the formula says. Pick and X and you get a constant
phase angle with respect to the zero degree reference. Pick a point
on a standing wave, and you get a constant phase angle (one of two,
180 degrees apart). If one rotates, so does the other. of one does
not rotate, neither does the other, at that point.

> That's what makes it different from a standing wave phasor
> which doesn't rotate with respect to the source phasor.

I disagree. There are differences, but that is not one of them.

>> Phasor rotation only applies to the phase change over length for a
>> traveling wave.
>
> No, that's wrong. Take another look at cos(kx+wt). Holding 'x'
> at a constant value, the phase keeps on changing.

No. the kx term is the phase term. Pick and X and the phase (with
respect to the zero phase reference freezes. The wave continues to
unfold in time, but with that fixed phase relationship to the phasor
reference.

> The traveling
> wave phasor is rotating with respect to the source.

Not at a point. at any point, there is a fixed phase relationship
withe the phasor zero degree reference.

> The standing
> wave phasor is not rotating with respect to the source, just
> as Hecht says speaking of standing waves: "The resultant

> wave it represents doesn't progress through space - it's a
> standing wave."

The standing wave is a mathematical concept that represents the super
position of a pair of waves that are going someplace. It represents a
case where two equal energys are being delivered in two opposite
directions, so no net energy moves. But waves continue to travel.

> You really need to get you a copy of Hecht's "Optics". It the
> best treatment of standing waves that I have ever seen - also
> best at superposition and interference explanations.

I don't need this reference. I have a form grasp of traveling waves
and their superposition.

>
> RMS#1*cos(A1) + RMS#2*cos(A2) = RMS(total)

That is not adding, that is scaled adding (with a possibility that one
or both scaling factors are negative). Do you get negative total RMS
current, if both cos(A) terms are negative?

>> There is no discussion of RMS envelope values.
>
>

I didn't mean that no one is dealing with RMS values, I meant that no
one disagrees (is discussing) RMS values. It is not a point of
contention.

>
> Sorry, the coil is obviously not the problem. Everyone understands
> how a coil works.

When did everyone agree on that? Last time I looked, you were
claiming that one could use the self resonant frequency as a way to
predict the phase shift through a coil at other frequencies (to some
rather open tolerance) with the assumption of constant time delay.
And then you tested (with EZNEC) a coil in a one way wave situation
and demonstrated a 5 to 1 change in time delay over a rather small
frequency range, then you dropped the subject of coils and claim we
are all talking about some mystery of standing waves. It is hard to
keep up.

> What everyone doesn't understand is how standing
> waves in a wire work.

That is a pretty broad claim, unless you are really speaking for yourself.

> That will be my topic of discussion from now
> on. But feel free to continue the coil topic with anyone else.

Okay. I won't mention "bug catchers" any more in posts responding to
you. Glad that's over. ;-)

today the elevator room on the roof is all relays, looks like a
frankenstin set from the 50's wouldn't be surprized if the relays are
actually from 50's either

my antenna is mounted on the wall (brick) of this room

currently i don't get any noise (electricial)

Just found out the building is thinking of adding new elevators and
modern controlers

so now i wonder, should i suspect that they are all rf tight in metal
housing's or a rf nightmare?

anyone have any experience w/how much 'noise'/hash they might throw ooff?

tnx

m

my original post specified one direction , figured that's until i can
rotate the building easily

but if the antenna of this type worked well /was practical past the
experiment stage wich was also specified as the point...

then a better way would be to just paint 4 , one for each side and use
a coax switch yeah thats cool

No - thank you for agreeing with me that your equation is too
simple to be useful. :-)

> That is not what the formula says. Pick and X and you get a constant
> phase angle with respect to the zero degree reference.

But that phase angle is not zero as it is for standing waves.
You seem to be talking in circles. How can the phase shift
between the traveling wave and the source reference ever be
zero at a point 90 degrees away from the source? If it cannot,
then you have evidence that the traveling wave is NOT identical
to the standing wave as evidenced by their different equations.

> Last time I looked, you were claiming
> that one could use the self resonant frequency as a way to predict the

Where have you been? I gave up on that idea long ago. I even posted
a Dr. Corum quote to that effect. You obviously need to look more
often.

Let's cut to the bottom line. You seem to believe that standing wave
current is identical to traveling wave current. If that's your point,
just say so. Otherwise, please tell us the difference between the
standing wave current and the traveling wave current which seems
obvious to me from the equations.

For general information on baluns and common mode chokes (called "current baluns" in the article), see http://eznec.com/Amateur/Articles/Baluns.pdf. For dimensions of air core chokes like yours, see the ARRL Handbook.

That's an interesting story about the W2DU balun. There must have been a huge amount of common mode current, and insufficient balun impedance.

>anyone have any experience w/how much 'noise'/hash they might throw ooff?

Hi Myles,

Most controllers I've designed with were always "zero crossing"
sensitive. That means they did not add RF trash by switching loads at
high (or even modest) voltage levels. This is not to say when they
turn off the load as some controllers are proportional (using a part
of the voltage cycle).

For motor control, I have had to use very, very fast servos which
could tolerate an overvoltage of 10:1 of its usual rating (hitting a
10V servo with 100V for instance). I didn't give much thought to the
hash created because this was in a printing plant where I had to
accelerate a page of paper in milliseconds (takes quite a bit of power
to do this).

Do a noise survey with a portable SWL receiver, and visit a lot of
buildings with elevators. You can do a dnoise/dz sweep as the
elevator climbs.

The coax used for every car radio of that vintage I ever saw (and I saw a lot) doesn't fit your description. It had a single, small diameter (#28 or so) wire rattling around loosely in a thin polyethylene tube, which was covered by a braided shield. The objective was to minimize the capacitance, but there obviously wasn't any control over Z0 or delay, since the small wire was free to move around inside the much larger diameter PE tube. There was no helically wound conductor. I think you might be looking in the wrong place for what you need. The connector fits your description, though.

Yet, EZNEC reports the difference in standing wave current and
traveling wave current better than you do.

EZNEC correctly reports the phase of the standing wave current to
be essentially zero all up and down a 1/2WL dipole using small wire.

EZNEC correctly reports the phase of the traveling wave current to
be the number of degrees away from the source in a traveling wave
antenna.

EZNEC clearly recognizes the difference between standing wave current
and traveling wave current. Yet you tried to use standing wave current
with its unchanging phase to measure the phase shift through a coil.
Standing wave current doesn't even change phase through 45 degrees
of wire. Why would you expect it to change phase through 45 degrees
of coil?

It was RG62 93 ohm coax. The connectors were called "Motorola"
plugs.

>> connectors. Why? What problem would the tape cause??
>
>Can't help you there.

My guess is that its biggest problem is that its presence will lead the user to the (false) conclusion that the connectors have actually been waterproofed by the application of the tape.

Based on all I've seen and read, vinyl electrician's tape does a lousy job of waterproofing outdoor connections. Its adhesive doesn't make a good waterproof bond with the connector surface (especially the threaded part), and both the adhesive and the vinyl itself tend to become brittle after a few seasons of exposure to direct sunlight. It'll leak like a sieve, and water will wick into your SO-239/PL-259 connectors and infiltrate the coax.

This tape does a decent job of protecting indoor electrical connections against accidental contact, but it's not good for waterproofing.

I generally prefer a two-layer approach - an inner layer of something adherent to do the actual waterproofing, and an outer layer to protect against sunlight exposure and weathering and abrasion.

For the inner layer, a self-fusing (self-amalgamating) rubber tape such as Daflex Stretch-N-Seal, Plymouth 122, or the like is a good choice. Some people prefer Coax Seal or various mastics, but some of these can be hell to remove from the connector and threads if you ever want to re-work it.

For an outer layer, a brush-on "liquid electrical tape" can be used. Another possibility would be a black cotton "friction tape" - 3M suggests their type 1755 as an outer protection layer for connections insulated with rubber electrical tape.

Even vinyl electrical tape can be used as an outer layer, I think - it doesn't have to be (or remain) waterproof, it just has to remain intact enough to protect the inner layer from direct sunlight.

If you really want to be thorough, insulate and waterproof with self-amalgamating rubber tape, add a layer of frictape for physical protection, and then overpaint with "liquid electrical tape".

Certainly not in older radios. I don't know what they sell nowadays.

I've seen that 'spiral' type of cable. They basically used the spiral as a means of maintaining the centre conductor in the average 'middle' of the hollow dielectric.

The combined inductance and capacitance of the old cable was somewhat critical but the older radios provided an antenna trimmer to compensate for the variations. The electrical model was essentially a "voltage probe" and doesn't necessarily follow common antenna/feedline rules and thought.

I said the phase was was fixed, not zero, at a given position.

> If it cannot,
> then you have evidence that the traveling wave is NOT identical
> to the standing wave as evidenced by their different equations.

I agreed that the pattern of amplitude and phase is different along a line for traveling and standing waves. But at any given point, there is a very similar kind of phasor (one with an amplitude value and a phase value) that describes what is happening at that point. That difference in amplitude distribution and phase shift with respect to position is what the two functions describe.

You keep claiming that there is something fundamentally different about the kind of phasor describing a single point (rotating versus non rotating), depending on whether the phasor is describing a point on a standing or traveling wave. That is where we disagree.

> Let's cut to the bottom line. You seem to believe that standing wave
> current is identical to traveling wave current.

At a point, it certainly can be. How current varies (amplitude and phase) over length is what is different.

> If that's your point, just say so.

I have said so as emphatically as I can, at least a half dozen times. You keep saying I am wrong and refer to rotating phasors and non rotating phasors. The only rotating phasor I know if is when a different (from the reference frequency and phase) frequency is described by phasor notation. That phasor rotates.

> Otherwise, please tell us the difference between the
> standing wave current and the traveling wave current which seems

> obvious to me from the equations.

I have, already. But here goes once again. A current produced by a traveling wave has a constant (RMS) amplitude along the line. The phase of the current (relative to some arbitrary phase reference) varies linearly along the line. If the line is a wavelength or more long, you can find any relative phase you want, just by moving along the line. There is energy moving along the line during this process, but no net (averaged over a cycle) current moving along the line. this is similar to how wave energy moves along the surface of water, without the water traveling along with the wave. The water just moves up and down as the wave passes along its surface. Likewise, charge moves back and forth, locally, within a half wavelength of the line as the wave passes, and the local current is a measure of the rate of this charge movement.

In the case of a pure standing wave, you have the super position of two equal and opposite traveling waves. The current (RMS) magnitude can vary anywhere from zero to twice the (RMS) magnitude of that produced by either of the two traveling waves. The RMS amplitude envelope will vary in a [absolute value of sine] way along the line. The relative phase of the current will have one of two values (the actual angle depending on what phase is chosen as the reference) that are 180 degrees apart. The phase switches between these two values each time you pass through a node in the amplitude distribution. There is no net energy movement, since the movement in one direction is canceled by energy movement in the other direction. There is, however, energy storage on the line.

Since the charge movement in a standing wave is the superposition of the charge movement of two traveling waves, in a standing wave, charge also moves back and forth only within a half wavelength interval of the line. And the standing wave current is the measure of the rate of change in this charge movement as it sloshes back and forth within that half wavelength.

If you have any corrections to any of this, please quote enough of what you what you are correcting for the context to be clear, and have at it. I want to get this right.

And in any case, the statement about EZNEC is incorrect. As I explained in a posting a short while ago, EZNEC has no awareness of nor does it make any use of traveling wave currents or voltages. It calculates only the total current from fundamental rules which don't involve traveling waves.

==========

A choke made of 8 turns, 6 inches diameter, has a resonant frequency around 21 MHz and has an impedance greater than 1000 ohms in the 20 meter and 10 meter bands.

Chokes are best wound neatly in the form of a single layer solenoid. Jumble wound choke coils can have funny effects.

For design of chokes made with coax cable download program SELFRESS from website below and run immediately.

So it's not just working on inductance. I'm still wondering why Cushcaft
recommends 8 turns and HyGain 12.

Reg thinks it's the tape's lack of water sealing. I have been using some
putty-like sealer on my 239s lately, but it is a mess to clean off when
disconnecting and re-connecting the coax - as sometimes required.

Thanks Bill.

The autopilot service manual I have shows a hand
drawn figure of the cable that indicates a curly or spiral twist
to the center conductor which appears as you stated to help
keep the center conductor in the middle of the tube. It also
mentions that the characteristics and length of the cable is part
of the tuned circuit, but doesn't give any data on the cable.

Like you, I'm sure I've seen that type of cable somewhere in
the past and thought it was in an automotive antenna application,
but it could have been elsewhere.

Thanks Roy. Now that you mention it, I do remember
the straight center conductor inside the much larger diameter
PE tube. The autopilot service manual I have shows a hand
drawn figure of the cable that indicates a curly or spiral twist
to the center conductor which appears to help keep the center
conductor in the middle of the tube. I also mentions that the
characteristics and length of the cable is part of the tuned circuit,
but doesn't give any data on the cable.

The connectors are like the connectors that were on the auto
radios back then. I wonder where those could be found today.
I can't seem to find them in any of the distributor catalogs I have.
Maybe a trip to an automobile junk yard.

Hi OM,

Lay down a layer of tape first.
Seal it with the sealer (much cheaper from flower shops).
Lay down another layer of tape.

So the phase is NOT the same between the standing waves and the
traveling waves proving that standing waves are different from
traveling waves. Like I said, we seem to be going in circles.

> I agreed that the pattern of amplitude and phase is different along a
> line for traveling and standing waves.

Then why are you arguing with me about it. That's what I also
believe. Your argument seems to be with the people who say,
"current is current".

> You keep claiming that there is something fundamentally different about
> the kind of phasor describing a single point (rotating versus non
> rotating), depending on whether the phasor is describing a point on a
> standing or traveling wave. That is where we disagree.

Yes, 45 degrees is fundamentally different from zero, is it not?
Let's see, the percentage difference is (45-0)/0.

>> Let's cut to the bottom line. You seem to believe that standing wave
>> current is identical to traveling wave current.
>
> At a point, it certainly can be.

No it isn't. It is the lack of knowledge that causes one to assume
that. More knowledge is all it takes to tell the difference. If
the current is everywhere in phase with the source current, it is
standing wave current. If the current is only in phase with the
source current every 360 degrees, it is traveling wave current.

> If you have any corrections to any of this, please quote enough of what
> you what you are correcting for the context to be clear, and have at
> it. I want to get this right.

We seem to be in basic agreement that traveling wave current is not
identical to standing wave current so what are we arguing about?

My comment above is primarily about standing wave current,
not about coils. Standing wave current phase cannot be used
to measure the phase shift through empty space, wires, or
anything else.

> waves.

EZNEC reports a different phase for traveling wave currents than
it does for standing wave currents. It does know the difference
although I don't know how it knows. It recognizes the difference
between a terminated line with no reflections and an unterminated
line with reflections.

The current reported by EZNEC for a terminated rhombic, for
instance, is clearly traveling wave current since the phase
changes with distance from the source.

The current reported by EZNEC for a 1/2WL dipole, for instance,
is clearly standing wave current since the phase doesn't
change with distance from the source.

The two kinds of currents are clearly not identical in either
EZNEC or in reality. They are only identical in some human
minds.

Sure it can. You just haven't yet figured out how to do it.

Here is a hint.
Standing wave current and voltage is not all the same phase.
Go far enough down the line, and there is a change.
How far is far enough?

My comment above is about 1/2WL dipoles and 1/4WL monopoles.
In those antennas, the standing wave current phase is fixed
around zero degrees. It cannot be used to measure delay
through anything.

The 180 degree phase shift in longer antennas doesn't add
any additional information. Since the amplitude is zero
at that point, we already have all the phase information
that we are going to get. We know at the zero point that
the forward current and reflected current are 180 degrees
out of phase.

Now it's "cannot be uneven?"

Your own words:
To which W8JI replied:

"The idea current is high in only the start of a coil is not correct.
Model an antenna with EZnec, and look at the load. Model a coil in any
software, and look at current. Read any textbook, even beginner's textbooks,
and see what they say. Measure a real antenna yourself!
......

You are like to call names, insult people, and argue rather than take the
time to learn basic electronics. This is in any book, including the ARRL
Handbook. If you look at HOW an inductor works, the current flowing in one
terminal ALWAYS equals the current flowing out the other terminal.

and.....

Measuring the current into and out of the loading coil with a small
thermocouple RF meter, I detect no difference This is in close agreement
with the model. " "

My mistake -- major difference. The W2AU balun was a voltage balun, so it had an extra winding connected between the two conductors. There's lots of opportunity there to produce huge fields in the ferrite.

> waves.

For anyone who thinks EZNEC doesn't report traveling wave currents
differently from standing wave currents, please download the following
files.

http://www.qsl.net/w5dxp/testx.EZ

This is a *traveling wave file*. EZNEC reports the nearly linear phase
of the current from 0 degrees at the source to 90 degrees at the load.
The file comes with a zero load in the center of that 90 degree run.
EZNEC reports the current's phase at 45 degrees at that zero load.

http://www.qsl.net/w5dxp/testy.EZ

Removing the resistive load from testx.EZ turns it into a *standing
wave configuration*. EZNEC reports the phase of the current close
to zero degrees all up and down the wire. The file comes with a
zero load in the center of the same wire as above. EZNEC reports
the current's phase very near zero degrees. The phase is near zero
degrees all up and down wire 2.

Contrary to what you have been told, EZNEC clearly reports the
difference between the traveling wave configuration and the
standing wave configuration. The traveling wave current phase
can be used to measure the phase shift through the wire (or
through a coil). The standing wave current phase cannot.

To summarize: For the traveling wave configuration, the current
magnitude is essentially constant all up and down the line while
the phase shifts smoothly from zero degrees at the source to
90 degrees at the resistive load.

For the standing wave configuration, the current magnitude
follows the familiar cosine envelope from source at zero
degrees to the end of the antenna at 90 degrees. The phase
of the standing wave current is unchanging near zero degrees
all up and down the wire.

Hi Dave.
A very interesting reply. Just recently I tried to get answers about
the actual mechanism for detecting "Gravity Waves".

I know I'm getting on a bit and retired, but I still get very supicious of claims based solely on advanced Mathematics which the "claimers" cannot explain in some terms which would be understandable to a person with a knowledge of Physics to say, Batchelor degree level.
Just how self checking is some of this work?
Some of the answers re LIGO seemed to imply that all 3 spatial dimensions are affected by the passage of a "Gravity Wave".
How does one detect that when your whole measuring apparatus is affected at the same time.
The other thing that has made me a little dubious has been that the claimed sensitivity of LIGO appears to have been downgraded by 2 orders of magnitude after it was completed in its first form.
Some while ago their site was actually downplaying whether they would ever detect a signal at all. Hopefully time will tell. In fact it would be nice to be proved wrong.

I think we are in very good agreement re the "Big Bang" theory.
The book of Genisis is the main source of inspiration for it I reckon!
Problem is so many astronomers who have sought for evidence for an alternative have had a very hard time from the establishment.
I have actually seen this myself at University level, with students getting marked down for just questioning the theory.

Of course I'm old enough to remember when "plate tectonics" was a heresy, and we all know what happened there.

Best Regards Cliff Wright.

Take 2 Yagis or verticals built with aluminum tubing. Both are identical except the tubing in one is twice the diameter of the other. Besides size, what will the property differences be between the two? Will they load up the same? I don't mean to be flippant, but this question has been on my mind for a long time and I couldn't find the answer. All comments appreciated. Thank you.

We're offering all the latest factory pressed high quality dvd movies, ps2, psp and xbox silvers with factory printed colour inserts at fantastic prices, whether for personal use or reselling. We're shipping worldwide with various shipping methods. For resellers, please contact us for bulk discounts.

For a complete list and prices, please email us at movieworld@time.net.my

(Please state the type of list that you want and tell us your location as the prices varies for different locations. If you're reseller, please state the quantity you wish to order per shipment and we'll quote you a wholesale price depending on the quantity ordered.)

* If you need references, we can provide them to you.

362. DELTA LOOP Antenna calculator

Newsgroup: rec.radio.amateur.antenna

Good morning gentlemen,

I have put online few weeks ago, a DELTA LOOP antenna calculator on the antenna-street web site.

This is easy to use html page, you just have to specify your work frequency and the number of elements that you want and the page

calculate all dimensions.

you can try it before to read the other part of this mail :
http://www.antenna-street.com/delta-loop-1en.php

(Note : other band will be available soon)

Well,

Now I would like to do better, and I would like to generate automatiquely a MMANA file from wich will be available directly by the soft to viw diagrams and most importants values (gain, swr, front/back dB etc.)

Actualy, MMANA file is like a txt file with an .maa extension. then I think that it could be possible to generate a file from a php page.

Maybe, some of you have already try to do it, then if you have any informations wich can help me to do it, it will be very appreciate.

Best regards,

Oli

Where is the entire context of that comment Yuri? You (and Cecil) have the habit of extracting things from context of a larger statement and exaggerating or putting a creative spin on what others say.

If you were saying the current is high only in the first few turns of a coil that is not in a high order self-resonance, that is incorrect.

If you were saying the current is high in only the first few turns your statement was incorrect.

If you were saying it had something to do with a cosign shape, your statement was not correct.

Saying the current is NOT high in only the first few turns in a loading coil in a working system is NOT the same as saying the current does not vary or cannot vary.

> You are like to call names, insult people, and argue rather than take the
> time to learn basic electronics. This is in any book, including the ARRL
> Handbook. If you look at HOW an inductor works, the current flowing in one
> terminal ALWAYS equals the current flowing out the other terminal.

That's true. The only thing that causes any differential is when the inductor has significant stray C to the outside world compared to the "through" impedance. Current can't just vanish.

I think that was explained at the same time. As I recall the conversation, you were claiming current followed the same taper as the antenna area it replaced and claiming only the first few turns had high current. You claimed coil Q didn't matter because most of the current was high only in a few turns.

I was trying to point out that idea, that the Q does not matter and the current is high only in the first few turns, is not correct by giving examples where we cannot measure the change with thermal couple meters.

> and.....
>

> Measuring the current into and out of the loading coil with a small
> thermocouple RF meter, I detect no difference This is in close agreement
> with the model. " "

Measurements are at:

http://www.w8ji.com/mobile_antenna_current_measurements_at_w8ji.htm

> You still don't know what are we talking about?
> Cecil is playing? Can you answer questions that he posted and I posted?

I've tried to answer every question Yuri, as have others. Does this
help clear up what I was trying to say?

As I recall you were claiming Q did not matter because current was high
only in the first few turns of a loading coil.

I pointed out Q does not matter as people expect for a different
reason. The real reason Q does not have the large effect on FS is
ground losses in the system swamp out the effects of coil ESR.

You said current difference was directly related to antenna area the
loading coil replaced, that the loading coil had to have the same
current slope as the area of antenna it replaced. If it replaced 80
degrees of antenna, it had to have the same current differential as
that 80 degrees of antenna. Is that correct, or did I misunderstand
you?

I was giving counter-points to that claim.

For example I posted this:

http://www.w8ji.com/agreeing_measurements.htm

Do you disagee with anything I say or Roy said when it is in context of
the overall discussion??

thanks all, that responded

guess i'll have to wait and see,

i wouldn't mind doing a survey however i'd have no way to really know in
the residential area i live which building have electroic elevator
controllers or not , can't tell from outside and can't really poke
around

OK i guess a better question might have been:

so if the controllers give off bad rf

what is the best way to 'shield' those boxes so they won't bother my
antennas outside the room?

presume that i can ground the cabinents myself if they are not already .

thanks

Everybody seems to understand how a coil works. Very few
people understand how standing waves work. There's no point
in discussing what people already understand. There's every
point in discussing what people don't understand.

That's essentially true for forward current and reflected
current. Demonstrably not true for standing wave current.
Even your own measurements showed that the current at one
end of the coil is RARELY equal to the current at the
other end of the coil.

If the lenghth of the elements is the same and diameter is thicker, then the antenna with thicker elements will resonate lower on frequency. You need to shorten the elements on the fat one to bring it back to resonance. The fater elements provide broader bandwidth too and take more punishment.

>> etc.

Now responding specifically to your request for a heap of explaining, you will find it in the George Brown paper I referenced earlier in this sub-thread. As that IRE paper from 1945 may be difficult to access now, you could refer to section 4-2 on the subject of cylindrical antennas in the "Antenna Engineering Handbook," 2nd edition (pub. 1984), by Johnson and Jasik -- from which this quote:

"In practive the antenna is always fed by a transmission line. ... The effective terminal impedance of the line (often referred to as the antenna impedance) then depends not only on the length and diameter but also on the terminal condition."

The text continues that for a MW monopole, the terminal condition consists of the characteristics of the ground plane. This section includes the plots of resistance and reactance for monopole radiators of various height to width ratios from George Brown's 1945 IRE paper.

The testx.EZ file has been renamed to:

http://www.qsl.net/w5dxp/TravWave.EZ

The testy.EZ file has been renamed to:

http://www.qsl.net/w5dxp/StndWave.EZ

The current reported by EZNEC for TravWave.EZ contains the term
cos(kz+wt) It's a traveling wave current, clearly not the same
as a standing wave current.

The current reported by EZNEC for StndWave.EZ contains the terms
cos(kz)*cos(wt) It's a standing wave current, clearly not the
same as a traveling wave current.

Current reported by EZNEC every 10% of wire #2 is presented in
the following table. The currents are obviously very different.
The phase of the traveling wave progresses from 0 to 90 deg
in 90 deg of wire. The phase of the standing wave doesn't
progress beyond 0.11 of of degree.

% along current in current in
wire #2 TravWave.EZ StndWave.EZ

0% 0.9998 at -0.99 deg 0.9996 at 0 deg
10% 0.9983 at -9.39 deg 0.9843 at -0.03 deg
20% 0.9983 at -18.23 deg 0.9454 at -0.05 deg
30% 0.9957 at -27.59 deg 0.8843 at -0.06 deg
40% 0.9949 at -35.96 deg 0.8023 at -0.08 deg
50% 0.9945 at -44.84 deg 0.7014 at -0.09 deg
60% 0.9945 at -54.2 deg 0.584 at -0.09 deg
70% 0.9949 at -62.58 deg 0.4528 at -0.1 deg
80% 0.9956 at -71.43 deg 0.311 at -0.11 deg
90% 0.9965 at -80.27 deg 0.1616 at -0.11 deg
100% 0.9976 at -89.14 deg 0.006073 at -0.11 deg

Some say "current is current". EZNEC disagrees. When
reflected waves are eliminated, EZNEC indeed does accurately
report traveling wave current. EZNEC reports the current
that is there, whether it is traveling wave current or
standing wave current.

I'm trying to learn how to graph the above current magnitude
and phase in Mathcad but not having much luck.

372. New program. Input Z of a loaded line

Newsgroup: rec.radio.amateur.antenna
Date: 2006-04-05 13:18:04 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <AMqdnbUlf9hOXq7ZRVny1A@bt.com>
Source record: 61614

NOW AVAILABLE ** New Program "INPUT_Z.exe"

This program calculates the often required input impedance, Z = R+jX,
of a coaxial transmission line when terminated with a load impedance
such as a radio antenna. It uses full classical transmission line
formulae and therefore avoids the errors inherent in the Smith Chart
at the lower radio frequencies.

Also calculated are line attenuation, reflection coefficient, angle of
reflection coefficient, SWR, power efficiency, and the line loss in
decibels in the presence of SWR.

Input data of frequency, line length, load resistance and load
reactance can be varied in small increments from the keyboard to allow
line behaviour to be observed. The diameter of the coaxial inner
conductor is also input, this being needed for calculating loss in the
line which affects input impedance.

Download program INPUT_Z (40 K-bytes) in a few seconds from website
below and run imediately.

Having spent 10 years in the elevator industry, you'll find that new equipment is mostly solid state with relays only controlling the safety circuit and motor controls. The controller is encliosed in a steel cabinet and as a result is ussually well shielded.

That being said, you did not indicate what type of drive system will be installed, SCR (DC motors), AC V3F Drive Etc or will the current drives be left as is. These could potentially be a source of noise depending on the manufacturer. Motor/Gen set (older DC drives) could be very noisy when the brushes are worn. Newer AC V3F drives could be noisy when DC injection is used for braking and holding the elevator at the floor (noise from the motor windings as they vibrate at who knows what frequency).

Most mechanics will be willing to share the info when you see them, coffee helps.

Remember the the elevator guys don't mind the sudden stops only the little jerks in between. Hi. Hi.

Now you are putting words in my mouth. The question and argument WAS and IS
about the current being (almost) equal (you claimed), or DIFFERENT (my et
other's claim) at the ENDS of the loading coil. You stated "ALWAYS EQUAL"
(Kirchoff, bla, bla...).
As illustration and description of the effect I observed on the Hustler
resonator was, that the heat developed from the bottom few turns. Like I am
so stupid to claim that there is high current only in your few turns?
Common' give me a break and fes up!! This is getting comical and pathetic.
.
Anyone can look up the original posting about the development of the "story"
at
http://www.k3bu.us/loadingcoils.htm
The whole dispute is summarized in Fig. 3 there, where it properly shows the
shaded area representing reality - current and area at the whip after the
loading coil vs. solid line representing misconception. (See degrees used
there?) Anyone, even Richard can see that graphic representation of white
area between the shaded area and triangular curve at the right, to see the
the difference in efficiency ignored by the "same current" crowd - the white
triangle is what you are missing!
If you don't get it by now, then you have serious problem.

Why don't you "gurus" repeat measurements, model it PROPERLY as solenoid or
loading stub (or look at Cecil's examples) within the quarter wave resonant
loaded antenna and tell me where and what IS WRONG on my web page. Step by

step and arguments please.
I am getting tired of this mental masturbation why it CAN'T BE when it IS.
I tought that by now "same currentniks" would get it, but looks like too much resistance to admit being wrong. Well, looks like really need for comprehensive article to explain it, describe the experiments that anyone can replicate and set the record straight. If you choose not to believe it, that is your choice and you can live with it, who cares, really. Except that some people parade as experts, gurus, engineers, when they are not. They have odacity to attack others about misinformation, when they have same on their web pages.
The even more sad thing is that apparently you influenced ON4UN to take the right information out of his latest edition of Low Band DXing book and replaced with your misinformation. It is all there in black and white, can't deny it, besides claiming being or having "JI Engineering" company, which you have no right to use that name or description, you ain't no engineer with degree.
One last question Tom: How many electrical degrees has 60 ft tall tower (10" face) with circular (or hex, or whatever you choose) top hat of 20 ft diameter at 1.8 MHz?
Can you answer Cecil's questions?
Obviously NOT without admitting that you were and are wrong. No more "proofs" needed like potshots at Cecil's ex wife.
I get better response from a brick wall when I hit it with hammer.
I really have no more to say, the rest will be in the comprehensive article published for anyone to get the picture and decide for themseleves if this is important or valuable for them, or not. (I promise, I am peeved now :-)

73 Yuri Blanarovich, www.K3BU.us

Rest is crap, twist and dance around the argument
With couple more comments that I could not resist. :-)

> If you were saying the current is high in only the first few turns your
> statement was incorrect.
>
Any dummy would know that it would be DISTRIBUTED along the coil, not in few turns that you picked or shorted out! Argument was ACROSS the coil, or at IT's ends. SAME (you) vs. DIFFERENT (me)!!!!!!!!!!!!!!!!!!!!!!!!!!!!
Capish?

Source record: 61618

The new elevator that was installed in my building here at the university,
puts out a large amount of noise on the AM broadcast band every time it
moves. I believe they are doing some sort of phase control on the motor with
little filtering.

>Everybody seems to understand how a coil works.

Crucially, you don't. The main property of a "coil" is inductance, and at the most fundamental level you do not understand what inductance does.

>Very few
>people understand how standing waves work.

Once again: crucially, you don't. You demand that ordinary electrical phenomena (like inductance and even current) change their properties or definitions in the presence of standing waves.

You are doggedly trying to make those two misconceptions cancel each other out. Won't work.

>There's no point
>in discussing what people already understand. There's every
>point in discussing what people don't understand.

I certainly agree with that... but we may differ about who we mean by "people" :-)

OK, I agree the current CAN be different.

Of course that has nothing to do with the amount of antenna the coil
replaces, it is a function of the physical construction of the loading
coil and how much capacitance the coil has from the coil to the outside
world compared to the capacitance terminating the loading coil.

Good. Then write your article and have it published. It would be easier
to understand your point if it was presented calmly and rationally in
an article. At this point I'm not sure what you are saying.

I would try putting up a vertical stripe on the building and then paint the radials on the sidewalk/street. This could be the ultimate in stealth. Make the radials look like a crosswalk or the center line down the street. You could even paint the curb, to make a no parking zone radial.

Awww, MAN,Cecil. I am sorry. I had no idea that you were putting up with a newsreader that can't follow threads, and in addition you have such a severe short term memory loss that you can't follow what's been posted within the past couple hours.

Bummer, man. Real bummer. I feel for you. It's a really bad combination.

We should be able to help you out with the newsreader problem if you want. I'm not so sure about the memory loss thing, though. It might help if you didn't try to keep so many balls in the air all at once, but I don't know that for certain.

I've patched together below (from the newsreader I use, which does keep track of all the branches of threads) what I wrote and what I was replying to in this particular sub-thread, so you can see it all in one place. If you'd like, I could do the same with the postings from other sub-threads here and from that other thread-that-wouldn't-die and email it to you, but that would be on a time-permitting basis.

Cheers,
Tom

Again, no quote from me. I have no idea to what you are responding
or even if you are responding to something I said today or last year.

I didn't say EZNEC doesn't give phase information. I said there is
no phase information in the phase information that EXNEC gives.
What is it about Gene's posting that you don't understand?

Please stop the mind fornication, Ian. I understand how a coil works
and I agree with you how a coil works in a lumped circuit or a traveling
wave environment. It's obvious that our basic disagreement is NOT about
coils but is, instead, about standing waves. If one doesn't understand
standing waves, one cannot understand standing waves in empty space, in
a wire, or in a coil.

Take away the coil leaving nothing but wire. You and I still disagree
regarding traveling waves Vs standing waves. Take away the wire and leave
nothing but empty space containing standing waves of light. You and I
still disagree regarding traveling waves Vs standing waves. Let's discuss
our point of disagreement, not something that we agree upon.

>> Very few people understand how standing waves work.
>
> Once again: crucially, you don't. You demand that ordinary electrical
> phenomena (like inductance and even current) change their properties or
> definitions in the presence of standing waves.

I just posted some tabular current data from EZNEC. EZNEC says that
current changes its properties in the presence of standing waves.
It's there in black and white for all to see. Please explain how
those two columns of data are identical.

The traveling wave current magnitude is constant over the entire
90 degrees of wire. The standing wave current magnitude is a cosine
function over that same 90 degrees of wire.

The traveling wave current phase changes linearly over the entire
90 degrees of wire. The standing wave current phase is unchanging
over that same 90 degrees if wire.

That doesn't look the same to me. In fact, one could make an argument
that traveling wave current and standing wave current are opposites
of each other.

>From where I am, Cecil, it sounds a lot more like everyone is bored to tears with standing waves, since they are nothing more than the result of adding together a couple travelling waves, and everyone here understood them LONG ago. In a linear system, one never needs to even mention "standing wave." A description of the travelling waves is all one needs. YMMV. You may be convinced that isn't true; I on the other hand am convinced--I am absolutely certain--that not everyone here understands how a travelling wave is actually supported on an antenna wire. That, to me, is a much more interesting topic: what is actually happening in the fields, and how do the fields arise from and in turn contribute to the motion and accumulation of charge on an antenna wire (and in a loading coil, which is part of the antenna wire).

As I've posted before, and as far as I know nobody's taken me up on it, it's quite enlightening to see an animation of the standing wave+travelling wave pattern that develops on a transmission line for various values of the ratio between the two travelling wave amplitudes. But once you've seen it, and likely even before, you know what you need, and (most of us) can move on

Cheers,
Tom.

My newsreader is indeed unthreaded. I remember what was posted
but sometimes not by who.

> We should be able to help you out with the newsreader problem if you
> want.

I prefer my newsreader unthreaded. I read postings in the order
in which they are received by my newsserver. Nothing else is ever
downloaded. If the context of a posting is not quoted, I never see it.

> I've patched together below (from the newsreader I use, which does keep

> replying to in this particular sub-thread, so you can see it all in one
> place.

I still don't see any technical content in those postings. I do
apologize if I have offended you but I still don't understand how.
But that is water under the bridge by now.

Sorry, the discussion has progressed beyond coils. Take a look at my
other posting about what EZNEC says about traveling wave current Vs
standing wave current and you will be up to date. Then you can use
your lumped-circuit theory to explain the major differences in those
two kinds of currents reported by EZNEC.

Source record: 61478

Just as we can make a short antenna resonant by adding a loading coil, and the loading coil may be placed anywhere along the antenna if an appropriate coil is chosen, we can make a long antenna resonant by inserting a series capacitance along the antenna wire.

When that physically long but electrically shortened to resonance antenna is excited and a standing wave pattern develops, what is the phase shift of the current through the loading capacitor? Is the standing wave current on the two sides of the capacitor different, in a manner similar to how it's different in a loading coil?

If not, why not?

Cheers,
Tom

Everyone *thought* they understood them. The assertion that "current
is current" proves that they didn't really understand them.

cos(kz + wt) is simply not the same thing as cos(kz)*cos(wt)
There is no trig idenity that will make them the same.

Even W7EL's assertion about EZNEC not worrying about traveling
wave current is wrong. When reflected current is eliminated in
the traveling wave antenna design, EZNEC faithfully reports the
traveling wave current proportional to cos(kx+wt).

Please comment on the tabular data that I posted from EZNEC.

And again, I apologize for offending you.

Is it not true that any two conductors can be modeled as either a
transmission line or a capacitor? At this level, there appears to be
analytic symmetry with a series loading coil.

In order to answer the question, one has to understand the
physics of standing waves. Most people don't understand the
physics of standing waves. Understanding the physics of a
capacitor embedded in a standing wave environment is pretty
much moot if one doesn't understand the physics of standing
waves. Please let's take first things first.

Using your reference
"Antenna Engineering Handbook," 2nd edition (pub. 1984),
by Johnson and Jasik
and having me carry your water of explaining, we find in figure 4-4
the correlation between resonance (the absence of reactance), length,
and diameter gives us a necessarily wide antenna of
13.9 meters

I cannot recall ever seeing any tower with a 45 foot diameter in a
commercial setting. However, that is not to say it doesn't exist,
merely that the odds for it are ridiculously astronomical.

If we browse the FCC database for other antennas to see how well your
reference "explains" how your quote above provides a resonance for
them, then we come across rather more astronomical odds being
fulfilled.

WFLF 75.00ï¿½ tall 540 kHz
requires a tower diameter of 364 feet =whew!=

KNOE 63.00ï¿½ tall 540 kHz
Let's just say that is so far off the charts it ceases to be
astronomic and becomes galactic in improbability. Basically this
reveals the breakdown in hyperbole's capacity to describe the metaphor
of improbability - especially in the face of these examples that
follow:

WGOP (POCOMOKE CITY) 63.00ï¿½ tall 540 kHz

WWCS 63.50ï¿½ tall 540 kHz

WYNN 65.50ï¿½ tall 540 kHz

KDFT 59.30ï¿½ tall 540 kHz

WXNH 56.30ï¿½ tall 540 kHz

WLIE 62.30ï¿½ tall 540 kHz

There's no point going further as this hardly exhausts one frequency assignment, much less the AM band.

The long and the short of it stands with my original statement:
>>Any
>>association between resonance, velocity of propagation, height, width,
>>etc. and something like our 118.60ï¿½ tall antenna needs a heap more
>>explaining than resonance, velocity of propagation, height, width,
>>etc. - but such explaining is a specialty occupation here in this
>>group.

Expanding slightly, it is absurd to attach a 90ï¿½ tall claim to an antenna simply because it has been resonated through adaptive measures. Unfortunatley, being absurd is also a specialty occupation here in this group.

But graphic representation gives rough idea to realize that it is not
unimportant or worthy ignoring.
If you wanna get precise metrics, stick the two versions of coil definition
in the EZNEC, generate the curves and compare areas under the curve from the
top of the coil to the tip. Then tell us that is negligible and was not
worth of this exercise.
I will get to it soon too.

I have a 40 ft vertical fed with coax that I am using today on 60 meters with excellent results. I have 34 radials under it now at about 43 ft.

I am wondering how I can use this antenna on other bands? 40, 20, 17, 15, 12, and 10 meters.

I am sure if I wanted to put it on 75m I would need to install a cap hat, and don't think I want to go through that but would like to see how I could use it else where?

Appreciate the help.

Nope. That's where. Autos. A piece of spiral plastic "rod" around the
solid wire center conductor to space it in the center of the over-sized-hole
dielectric. I thought it was also a "Motorola" connector, but didn't want
to sound arrogant (still working at the circle M Ranch, you know). The AM
receiver antenna was (is) nothing more that a capacitive probe hooked to the
input, so the smaller the loading cap the better.
Gee, if I shill have some around, perhaps some experimentation to determine
the Z0 ... OK ... project 9,735, on the list for retirement. (yea, right)

73, Steve, K9DCI

I only saw it referred to as low capacitance cable. Don't know if the Z0
was specified

One of the engineers at Delco told me it was RG-62, and 93 ohms when
I was going to their annual car radio training back in the early '70s.
IBM also used RG-62 on their coaxial computer networking, but they used
BNC connectors.

With a straight monopole, anything over 5/8 wavelength is
not a good DX radiation pattern. So if you are into low
angle radiation, the rule-of-thumb upper frequency limit
for a 40 ft. monopole would be about 585/40' = 14.6 MHz.
It would work well on 20m and deteriorate as the frequency
increases above 14.6 Mhz.

Scott,

On frequencies higher than 20-meters I doubt you not will be please
with performance above 20-meters for a 40-foot vertical - unless you
are primarily interested in talking to airplanes - as most of your
power will be launched at high angles.

I have a nice dual-band (40/20-meter) vertical described on my web
site at http://k6mhe.com/files/DualBandVert.pdf which you may find of
interest.

The automotive coax I'm familiar with isn't RG-62.

Like automotive coax, RG-62 has a thin walled hollow insulating tube. But RG-62 has a polyethylene "string" which is helically wound around the center conductor to keep it centered in the hollow tube. The coax in every old automotive installation I've seen lacks this PE "string", so the center conductor is free to flop around inside the hollow tube. The effect of the "string" is to make RG-62's Z0 constant and predictable, and it will also increase the capacitance somewhat. Constant Z0 isn't important for the automotive application, and low capacitance is important.

It seems to me the center conductor is smaller in the automotive coax than in RG-62, also.

> is obtained through the evanescent mode and optical couplers just like
> RF couplers work on the exactly the same principle.

I'm told that this approach is relatively easy to detect in that it requires a fair amount of mechanical motion to achieve. Single-mode fiber is often used to detect minute changes in, e.g., bridges, and the idea is that -- while there may be other causes of significant mechanical motion to a fiber -- detecting it in the case of a secure line is cause for investigation.

I've also been told, however, that you can use completely non-invasive (mechanically) techniques to sniff fiber... something involving the back-scatter of neutrons or somesuch. Don't know how much of that was science-fiction vs. readily doable with the funding of a major government, though.

I have not stated that an unloaded broadcast monopole of any physical height should be made self-resonant, or even needs to be, for efficient radiation. Very few broadcast monopoles are. The ones that aren't are matched to resonance and the transmission line Zo by a network at the antenna feedpoint, as I also stated.

What I wrote is that a radiator of "90 electrical degrees" when shown in the FCC database is NOT self-resonant, and referred to the experimental data from George Brown, and the work of Johnson & Jasik to confirm what I wrote. Kraus, 3rd edition, Ch 14 has the mathematical analysis to support this, also. NEC shows this effect, as well.

The rest of the examples in your post are based on your invalid assumption, for which my response is given above.

I should like to know the velocity factors which occur on various twin-balanced transmission lines. We have -

Open wire lines with infrequently spaced, flimsey spacers.

450-ohm ladder lines of various sorts.

300-ohm lines spaced with a thin continuous web.

130-ohm lines with two insulated wires stuck close together like twin speaker cable.

75-ohm lines embedded in a solid eliptical-shaped polythene.

I daresay some of you have made measurements at one time or another. The more data received the better. I can then take averages.

Thank you.

Reg, G4FGQ

Our basic disagreements are about coils *and* current *and* their behaviour when standing waves are present. There's no point in switching the discussion to cover only part of those topics.

I've only measured two of them, Reg. I measured "450" ohm
ladder-line VF at approximately 0.9 and "300" ohm ladder-
line at ~0.8. I was surprised since I assumed it would be
opposite those results.

You are trying to tell me what I think when you have no clue
as to what I am thinking. Excuse my French, but that is called
mind-fucking, Ian. Please cease and desist from that practice.
The only ethical and honest thing you can say about my postings
is, "it seems to me that you are saying or thinking such and such ..."

> Our basic disagreements are about coils *and* current *and* their
> behaviour when standing waves are present. There's no point in switching
> the discussion to cover only part of those topics.

Not switching the discussion to the only salient point of disagreement
will obfuscate the discussion. If that's what you want to do, then
your reasons for doing so are quite obvious, and readers are likely
to assume that you are not interested in technical facts at all but
more interested in preserving your omniscient guru status through
obfuscation.

So the real question is: Why have you avoided responding to my
tabular current posting based on EZNEC's take on traveling wave
current Vs standing wave current? Some may assume from that lack
of response that you are afraid to address the technical facts
as are W8JI and W7EL.

If you guys are so right, why are you afraid of discussint the
technical issues that I have posted?

==========
Cec, the lower value for 300-ohm ladder line, compared with 450-ohm
ladder line, is what I would expect. Thanks for the figures.

It is the increase in capacitance between the two wires, due to the
permittivity of the insulation and because the wires are closer
together, which causes the decrease in velocity.

Reg.

414. Re: Question about auto antenna cable and connectors

Newsgroup: rec.radio.amateur.antenna
Date: 2006-04-05 20:57:14 UTC
From: Ronnie <rhughes4-removeme@swbell.net>

Roy is right. I looked up RG62 and this is not the cable I have.
Here's what the autopilot service manual has to say about this
cable.

"The coaxial harness assembly CD-1, 2 and 3 is manufacued to specific
lenghts and since the cable is a part of the tuned circuit, these lengths
must
not be altered. The sensor leads are made of very fine wires that are fed
through a hollow insulator. Note that the fine wire has been coiled to
provide flexibility and reduce the possibility of beaking and causing an
open in the circuit."

The diagram shows a hollow tube with a fine wire that is coiled running
through it, a braid style shield over the hollow tube and an outer jacket
over the braid. It seems to be a variant of the auto coax where the fine
wire center conductor has been coiled instead of being left straight.

Thanks for all the help with this, but don't worry yourselves about it.
I have all the orginal pieces with connectors intact, but I was hoping
to find the technical specs on the cable so I could understand the
cable's impact on the resonant frequency.

Ronnie

What's this current phase shift through a capacitor?

I believe it is a voltage phenomena. The incident and reflected waves induce voltage at the capacitor terminals. In HF systems the capacitor is very physically small, and the lumped model should suffice. [There is no long length of wire to confuse the model].

A vertical antenna has a characteristic impedance, depending on ground effects, proximity effects, etc. of somewhere between 200 and 500 ohms, typically 350 +/- ohms.[It's been a long time since I calculated the nominal value, but for basic understanding just use antenna Zo]. Apply a stimulus to the antenna and the signal propagates along the antenna governed by it's Zo. [Not the Zo of the transmission line at this point]. So, at the incident input side of the capacitor there is a v that is the integral of current [incident] times time. This voltage lags the incident current. At the reflected input side there is a voltage that is the integral of I [reflected] times time. This current is the reflected value and spatially delayed by the propagation time from the capacitor to the end of the antenna. This voltage lags the reflected current.

The net voltage across the capacitor is the spatial sum, NOTE: Spatial Sum, of the two voltages. Assuming To at the incident current input to the capacitor then the problem is simplified to the spatial [propagation delay to the end of the antenna and return].

So, current phase shift in the capacitor may be asking the wrong question.

I read somewhere that hydrogen dissipates quickly in the outdoor air and is unlikely to ignite. I also read that the Hindenberg was coated with aluminum powder. After it exploded, the coating on the other airships was changed and there were no further accidents. But there is surely more to that story.

It would be interesting to know the relative costs of the two gases to the consumer. It would also be interesting to know about safety precautions common to both gases and how to compute practical lifiting capacity. .

420. Must 300 ohm feedline be kept completely clear of contact w anything?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-04-05 23:33:13 UTC
From: Thomas anonymous <Thomas.anonymous.25toz8@news.radiobanter.com>
Message-ID: <Thomas.anonymous.25toz8@news.radiobanter.com>
Source record: 61429

How critical is it to mount twinlead feedline (300 ohm TV ribbon type) so that it doesn't come into contact with anything? Obviously, with bare ladder-line type feeders it's absolutely essential (to prevent shorting!), but what about the insulated type of 300 ohm twinlead --- can you have it run next to wood, say, or even metal as long as there is no conduction between the inner conductors and anything metal that might cut through the insulation? I've heard that Home Depot has a newer type of 300 ohm twinlead that is oval, almost circular in cross section because it is foam filled and thus if it were to be lying on top of something, or next to something, there would be an extra 'cushion' between the current carrying wires inside and anything outside the wires so would that mean it would be OK to run this type feedline up against the wall of a house? Or would it also be absolutely essential to somehow mount it so that it is free and clear of anything?

421. Unknown coax id help?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-04-05 23:36:26 UTC
From: Ken Bessler <kg0wx@NOSPAMyahoo.com>
Message-ID: <6wYYf.4689$fS6.618@dukeread11>
Source record: 61512

The label on this coax reads:

"CFD200-NL LOW LOSS 50 OHM COAXIAL CABLE COMMATE/PEWC 3D"

All I could find was a spec saying it has a VF of .83 and I measured
the OD (0.195"). The cable is very stiff for it's size - like 9913 almost.

Anyone care to guess? I'd love to take it apart (it's a RP-TNC - N Male 5'
pigtail) but it's such a nice job I don't want to. Maybe it's a copy of
LMR-200?

I'll be using it to connect my 802.11b/g equipment (100mW, 2412mhz) to the
main feedline (30' flexi 4xl with clamp type N connectors feeding a 16 el
collinear antenna at 25' agl).

Help?

Hi Yuri,

But it gives nothing of that impression at all. If it were important,
then you could give me solid numbers instead of an art review.

>If you wanna get precise metrics, stick the two versions of coil definition
>in the EZNEC, generate the curves and compare areas under the curve from the
>top of the coil to the tip. Then tell us that is negligible and was not
>worth of this exercise.

Yuri, I did that two years ago. You have yet to disagree with the
pitiful difference and the best chance of you doing it yourself is:

>I will get to it soon too.

I heard that two years ago too.

You don't give any impression that the topic at hand is nearly as
important to you as duking it out with Tom. But if after two years of
swinging and you still haven't connected a solid KO, don't expect us
to hand you a TKO (because your Technical part is a marshmallow
punch).

Cecil, you've proven over and over again that you're not
interested in technical discussion. You are interested in
argument and a crude sort of digladiation where you do the
verbal equivalent of kicking, biting, hitting below the belt,
rabbit and sucker punching, throwing sand, popping
steroids and amphetamines,and shooting people in the back.
All this is being duly noted by the participants who by
now have consigned your theories to the fractal junk pile.
Come back when you're really interested in a technical
discussion. The kind of discourse you enjoy is only fit
for ending marriages.

"Richard Clark"wrote
> Sounds like you have a problem following context.

No, from your posts IMO it is YOU who has a problem with your reading comprehension, and/or possibly your professional integrity.

I posted "The effective electrical length of a MW monopole radiator determines its resonant frequencies, and that must include the velocity of propagation along the structure -- which is a function of the height AND width of the radiator (mainly), and the operating frequency." I have also posted several references in the literature which support this in technical detail.

You then posted "3. this does not explain how a 118.60ï¿½ tall antenna comes to be resonant ," and several ridiculous examples of broadcast tower widths of 364 feet and more that you falsely attribute as flowing from my statements.

Contrary to your recent post, I have never written anything that remotely implied that your 118.60 degree radiator, or a broadcast radiator of any other length can/should be made self-resonant by the use of an impractical ratio of width to length. I have posted several times that (conventional) broadcast radiators that are not self-resonant are brought to resonance at the feedpoint by the use of a matching network there.

If you can find ANYTHING in my posts on this subject to support your statements, please quote them to the NG. Otherwise I suggest you let this thread close, and (hopefully), learn from it.

I'm not at all sure what all the hoop-lah following Richard Fry's
posting reproduced below is all about. What Richard wrote is accurate,
as he says confirmed by NEC simulation, and also from the
King-Middleton second-order theory of linear antennas. From the date,
it sounds like Brown's paper was a confirmation of the theory,
actually. An antenna resonant at 95% of a freespace quarter wave,
above perfect ground, would be about 150 times as long as its
diameter--a 75 meter tower about half a meter effective diameter. NEC
gives slightly different numbers, but perhaps more interesting is that
even for VERY thin wires, the resonant length is noticably shorter than
a freespace quarter wave. A wire a millionth as thick as it is long
still shows resonance more than a percent shorter than the freespace
wavelength.

It's an interesting observation, but I thought everyone (with a serious
interest in antennas) would know about it.

The effect at full-wave dipole resonance/half-wave above a ground plane
is considerably more pronounced, over ten percent for a moderately
thick antenna.

Cheers,
Tom

Richard Fry wrote in Message-ID: <44326790_1@newsfeed.slurp.net>:

"Richard Harrison" wrote:
> It is the convention to describe AM broadcast towers in electrical

> Formula given is:
> Height in electrical degrees = Height in feet X frequency in kc X
> 1.016 X 10 to the minus 6 power.

If electrical length is defined as the physical condition where
feedpoint
reactance is zero (e.g., resonance), then the true electrical length of
an
AM broadcast radiator on a given frequency is a function of the
physical
length AND physical width of that radiator. This was proven
experimentally,
and documented by George Brown of RCA Labs in his paper "Experimentally
Determined Impedance Characteristics of Cylindrical Antennas" published

in
the Proceedings of the I.R.E. in April, 1945. It also has been proven
in
thousands of independent measurements of AM broadcast radiators ever
since.

The curves in Figure 3 of Brown's paper show the feedpoint reactance
terms
of the base impedance of an unloaded monopole of various lengths and
widths,
working against a nearly perfect ground plane. Those values cross the
zero
reactance axis at physical heights ranging from about 80 degrees (for
the
widest radiator) to about 86 degrees for the most narrow.

Brown calculated height in degrees as (Physical Height in feet x
Frequency
in kHz) / 2725 . Brown's equation, the one in the Harold Ennes quote
above, and the one that the FCC uses in their published data all define
only
the relationship of the physical length of the radiator to its
free-space
wavelength in degrees at that frequency.

But clearly these lengths in degrees do not define the self-resonant
length
of that radiator. The self-resonant length, invariably, will be
shorter by
several percent. This fact is easily confirmed by simple NEC models,
for
those who want to probe into George Brown's data.

Tables relating a single value of base impedance as typical for towers
of
various electrical heights (only) must be read with an understanding of
the
above realities. For example, Ennes' list shows a tower of 90
electrical
degrees to have zero reactance. But Brown's 1945 paper and a great
amount
of later field experience shows that this is incorrect, for the
conventional
use of this term.

Are the odds zero that it might be your misunderstanding?

Please respond to this previous posting:

The testx.EZ file has been renamed to:

http://www.qsl.net/w5dxp/TravWave.EZ

The testy.EZ file has been renamed to:

http://www.qsl.net/w5dxp/StndWave.EZ

The current reported by EZNEC for TravWave.EZ contains the term
cos(kz+wt) It's a traveling wave current, clearly not the same
as a standing wave current.

The current reported by EZNEC for StndWave.EZ contains the terms
cos(kz)*cos(wt) It's a standing wave current, clearly not the
same as a traveling wave current.

Current reported by EZNEC every 10% of wire #2 is presented in
the following table. The currents are obviously very different.
The phase of the traveling wave progresses from 0 to 90 deg
in 90 deg of wire. The phase of the standing wave doesn't
progress beyond 0.11 of of degree.

% along current in current in
wire #2 TravWave.EZ StndWave.EZ

0% 0.9998 at -0.99 deg 0.9996 at 0 deg
10% 0.9983 at -9.39 deg 0.9843 at -0.03 deg
20% 0.9969 at -18.23 deg 0.9454 at -0.05 deg
30% 0.9957 at -27.59 deg 0.8843 at -0.06 deg
40% 0.9949 at -35.96 deg 0.8023 at -0.08 deg
50% 0.9945 at -44.84 deg 0.7014 at -0.09 deg
60% 0.9945 at -54.20 deg 0.5840 at -0.09 deg
70% 0.9949 at -62.58 deg 0.4528 at -0.10 deg
80% 0.9956 at -71.43 deg 0.3110 at -0.11 deg
90% 0.9965 at -80.27 deg 0.1616 at -0.11 deg
100% 0.9976 at -89.14 deg 0.0061 at -0.11 deg

Some say "current is current". EZNEC disagrees. When
reflected waves are eliminated, EZNEC indeed does accurately
report traveling wave current. EZNEC reports the current

that is there, whether it is traveling wave current or
standing wave current.

Hi Joel,

You mean the actual abrasion preceding the bonding?

>Single-mode fiber is often used
>to detect minute changes in, e.g., bridges,

Yes, I am very familiar with those applications. They are wholly
devoted to that use, not data.

>and the idea is that -- while
>there may be other causes of significant mechanical motion to a fiber --
>detecting it in the case of a secure line is cause for investigation.

You are describing paranoia. Somehow, I think in the heady dot.com
days when 95% of this stuff was put into surplus, absolutely no one
worried about this. OK, maybe someone, no one here knows who they
are.

>I've also been told, however, that you can use completely non-invasive
>(mechanically) techniques to sniff fiber... something involving the
>back-scatter of neutrons or somesuch. Don't know how much of that was
>science-fiction vs. readily doable with the funding of a major government,
>though.

Heh heh, that was probably dreamt up by the paranoid ones. Experience
has always shown that "security experts" (those who roll their own)
are the most vulnerable. You don't need advanced degrees in
interstellar physics to read their mail. Simply look at the DVD
encryption model. It was busted by 35 lines of code. Look at
Homeland Security, and then think Katrina.

Hi Tom,

At the time (ca. Hitler), the US dominated the world in Helium
production and we withheld stocks from Germany. Their choice of
Hydrogen was not strictly due to its lifting capacity.

Computation is called buoyancy. You start with the volume of the gas
sack. Fill it with air and weigh it. Replace the air with anything
else, and weigh it. The difference is the lift. To skip the scales,
and simply find the weight, you compare molar weights. Look 'em up on
the old fashioned Periodic Table of elements.

Unlike electrical conductivity, permeability is often a highly non-linear
quantity. Most coil design formul&#65533;, however, pretend that it is a linear
quantity.

==========

My question is-

If I wind a transformer using the specified A sub L and then use that
transformer in a receive antenna where the voltages are very small, wouldn't
I be low on the curve and cause the transformer to function poorly
especially at the lowest frequency of the design?

Mike

PS Thinking about a Flag antenna, which has a small output signal.

Al is usually the value for low flux density. That is, it's the value you'll have when the flux level is low. Permeability will drop from there at high flux levels.

If you're making a broadband (untuned) transformer, you only need to insure that the winding impedance is high enough. If you design it to have adequate impedance at the lowest frequency, you should be ok for frequencies above that. If you're making a tuned transformer, you'll probably be using either powdered iron core or a ferrite core with a big air gap in the magnetic path like a ferrite rod. Either will withstand many orders of magnitude of flux density above what a received signal will produce before there's any noticeable change in permeability.

The assumption of constant permeability is often a reasonable one. Change in permeability with flux density is certainly nothing you have to worry about in a receiving application unless you've got a lot of turns and a lot of DC current in the winding.

What a tedious imposition to have to repeat correspondence, but if
that is your price, then only one example in full:

>
>>>KYMN 118.60ï¿½ tall 92.3 meters tall 1080 kHz
>>>re:
>>>http://www.fcc.gov/mb/audio/amq.html

The FCC recitation of these facts is one such MW monopole radiator.

We proceed to YOUR reference:
>>"Antenna Engineering Handbook," 2nd edition (pub. 1984), by Johnson and
>>Jasik
specifically to YOUR point
>>a function of the height AND width
which is manifest in figure 4-4.

If you cannot resolve that graph, and for others reading, it shows a
family of curves constructed on the basis of A/D which is elsewhere
described as Length over Diameter.

For a radiator of 118.60ï¿½ tall the only curve passing through zero
reactance is assigned an A/D of 20. A is already known and is
118.60ï¿½. It then follows to satisfy the A/D of 20 drives the value of
D to be 5.93ï¿½ which for a wavelength of 277.8 meters works out to be a
diameter of 4.58 meters (corrected from my computational error
earlier).

In EZNEC the thin wire model reveals a source Z of:
Impedance = 97.63 + J 371.5 ohms
which confirms against figure 4-4's example for an A/D=1000

I don't know the validity of forcing the radiator to the 4.58 meter specification, but EZNEC clearly shows that move drives out reactance with a source Z of:
Impedance = 133.8 + J 78.91 ohms
This, too, conforms to figures 4-3 and 4-4 to within acceptable limits of error. If that offends your sense of accuracy, we can take it outside.

I see no need to proceed further along lines that clearly follow the precepts offered by J&J.

Now, returning to the diameter that has been proven to be necessary to resonate this instance which you dismiss as "ridiculous examples," my comment about seeing very few towers that exhibit this magnitude of diameter (the size of my living room) still stands as unimpeached.

Going further into your cavalier dismissal of "ridiculous examples" we find that there are a forest of very short antennas in service. My link provides so many in one frequency assignment that the force of numbers cannot be denied so simply, and certainly when lacking technical rebuttal. Those offered such as:
>>WXNH 56.30ï¿½ tall 540 kHz
when run through the same exercise above (YOUR reference, YOUR claims) reveals a necessary A/D of LESS THAN 5. The simple math resounds with the implications of necessary diameter to resonate this through (YOUR claims YOUR quotes of):
>"The effective electrical length of a MW monopole radiator
>determines its resonant frequencies, and that must include the velocity of
>propagation along the structure -- which is a function of the height AND
>width of the radiator (mainly), and the operating frequency."

For a wavelength of 555.6 meters, that A/D resolves D to a value of 111 meters (and this arbitrary selection of A/D=5 is NOT the necessary value it is less) or the 364 feet. I see no reason to impeach J&J by attempting this with EZNEC for a result that is so obviously absurd in the real world to achieve.

This absurdity reveals that it takes much more than these intellectual shenanigans of height AND (YOUR emphasis) width to resonate a short antenna. Please note THIS context which has been part and parcel to these threads for more than 1000 pieces of correspondence.

Hence, the suite of recited example antennas clearly exhibit an expressed height, in degrees, that are strictly an expression of their physical height in terms of wavelength, and have nothing to do with their being resonant OR non-resonant. It is equally clear that in their service, there have been means made to resonate them, and that does not impact their height description either.

Richard Clark, KB7QHC

p.s.
>No, from your posts IMO it is YOU who has a problem with your reading

>comprehension, and/or possibly your professional integrity.
This is an amateur forum, and I don't trade on my professional credentials to retail them as proof. Reading comprehension is best left to the rest to evaluate; and as many express confusion, or difficulty with my writing, none have challenged my data. I can live with their confusion, and justify that with a quote from Dr. Samuel Johnson, courtesy of his biographer James Boswell:

Johnson having argued for some time with a pertinacious gentleman;
his opponent, who had talked in a very puzzling manner, happened
to say,
"I don't understand you, Sir"
upon which Johnson observed,
"Sir, I have found you an argument;
but I am not obliged to find you an understanding."

I saw both types on car radio antennas, and some was clearly marked
RG-62. Both types meet the original RG62 specification, they just use
two different methods to minimize dielectric losses, like fused disk
hardline used in CATV and other applications that require low loss
cabling. Also, why would one of the Delco engineers who designed their
car radios lie about the coax they used? He was explaining the then
brand new AM/FM/8-track combo when I asked a number of questions about
the RF front end. As usual, you will continue to believe whatever you
want to.

I'm just trying to extend my wireless access point's range so I
can go to a park nearby, operate /qrp/portable with my K2 yet
still be able to check the dx cluster, email, etc. So far, I've
equipped my ThinkPad with an Atheros high performance WiFi
internal radio driving a pair of 4 element coaxial collinear antennas,
acquired a V4 Linksys WRT54G router and designed & built a
16 element base version of the collinear antenna.

I've got the needed parts enroute to put the base antenna up 25'
and the firmware needed for the router to do all sorts of things, like,
increase the TX power, go to client mode for rf survey's, stuff like
that.....

The pigtail antenna lead is just to make the transition from N
connectors to the RP-TNC that the router uses and to protect
the router from excess cable strain from the Flexi4xl coax.

Just a way to spend money and kill time and - oh yea - learn
some neat technology along the way.

Next week, kids, we'll discuss the pro's and con's of 160 meter
quad equipped diversity antenna systems.......

lol!

Richard, Richard, Richard. Clark, that is. Shame on you. Get a grip. Richard Fry's list simply showed that in the FCC listing, the length in degrees is calculated on the basis of freespace speed of light. In addition, he was pointing out that resonance is not at 90 degrees, calculated in that manner. THAT point is supported by other data. The FCC data didn't come into play with respect to that point. All that was obvious to me.

Do you disagree that resonance of a monopole over a ground plane is for a length somewhat shorter than c/(4*f(resonance))? If you do, then let's have a discussion about THAT.

Cheers,
Tom

I agree with Roy that the linearity of coils wound on powdered iron cores is unlikely to be a problem for you. A while back, I had occasion to question if some filters we use, made with small powdered iron toroid core inductors, were causing distortion, so I built up some similar filters with air-core coils and very good capacitors that I knew would not distort. The result was "no change". That corresponds in this case to third order intercepts in excess of +50dBm, which would be considered at least pretty good by all but the fanatics for use in receivers. I don't know how much in excess of +50dB, because that was about the limit of what I could see in that test. Also, I know that the broadband transformers used in the best H-mode mixers have allowed those mixers to perform at similarly high--and higher--third order intercepts. I suppose those transformers are transmission-line types, wound on ferrite cores.

Cheers,
Tom

No, just 37 feet of RG8X. But that's enough to have significant losses
when the SWR is up in the 30-60 range, which it easily reaches if I put the
wrong whip on the mount.

The thing is, we know the universe is expanding. That implies very
strongly that it has a definite, very hot, very dense beginning. The
rest of it is the technical details.

You don't want unbalanced coupling between one side of the feedline and
something else. That would unbalance the feedline. You MAY not want the
impedance bump that comes with equal coupling on both sides, though that
might be tolerable if you're tuning the line anyway. And you don't want
lossy coupling of any kind.

Not to nit-pick but the permeability of nearly all powdered iron formulations actually rises with increasing flux levels (AC) and then falls off. For #26 material (u=75), the effect is very much exagerated with the permeability increasing nearly 300% at ~5000 Gauss and then falling very quickly. However the permeability does drop for any value of DC bias current and larger DC bias currents produce greater reductions in permeability.

Hi Tom,

Do I disagree? Now, there's a classic line that too frequently
litters these threads.

I've offered many antennas that are spectacularly (considering their
commercial application) shorter than quarterwave (the same size, and
longer too). These shorter antennas easily embody your comment above.
Now what is the THAT that seems to bear discussing that I haven't
already covered twice? Three times is not a charm.

In general there is a magnetic/electric field between the conductors in
twinlead feed line. If this field is in contact with a metal or other
conductive surface it will distort the impedance of the wire. Twinlead
with the round surfaces between the conductors will keep the field out
of the way of any surface the twinlead is resting on. This helps to
maintain the constant 300 ohm impedance of the twinlead. That is why tv
leadin uses standoffs to restrain the wire from the antenna to the
receiver/transmitter.
There is nothing wrong with using twinlead. It's cheap, light weight and
easy to install.

Thanks for the correction. The permeability monotonically drops with increasing coercive force (H), but rises as you say with increasing flux density (B) over some range of flux densities. This is true for ferrites also.

I happened to find a piece of the automotive cable -- complete with connector -- in my junk box, which I'm pretty sure was cut from a replacement antenna probably purchased in the '70s. This particular cable lacks the PE "string", but the ~#31 center conductor is crimped in a sort of zig-zag shape to keep it in place in the hollow tube. The aviation cable apparently has the center conductor bent into a (presumably loose) helix for the same purpose. I've never seen RG-62 cable without the PE "string", but don't have any trouble believing that someone might manufacture it without the "string". I also don't have trouble believing that some auto manufacturers might use RG-62. Although I saw a lot of auto installations in the '60s, when I moonlighted repairing such things, I never saw RG-62. But I certainly didn't see anywhere near every possibility, and I could have missed seeing a marking.

You can get aluminum 6061 3/16" rod at most metal suppliers or scrap metal salvage yards. Check the yellow pages. If they don't have it in stock they will usually order it for you. I was quoted a price of about $10 US for 1" X 12' square tubing, and about $3-4 for the 3/16" X 12' rod stock.

Hope this helps,

Thanks, Wes, for the "Ladder line" pdf. I really enjoyed reading it.
Both factual and entertaining.

The impedances Zo of the nominal 450-ohm lines were all on the low
side. I wonder if this was due to the manufacturer's ignorance?

Did he use the usual ratio of wire-spacing to wire-diameter to deduce
Zo and forgot to multiply Zo by the VF to reduce Zo to the value he
actually achieved?

Then, it he ever measured Zo, he thought his measurements must be in
error and just carried on making the stuff.

Thanks for the data.

Reg.

If you muliply that loss out, it's about 17 dB loss per 100 feet. That would be considered pretty lossy...but...since you're only using 5 feet, it's probably not going to be a deal breaker :) Andrew 1/2" hardline is about 3.6 dB per 100 feet (granted it is NOT RG-58 sized!)...

hi

Hoping someone might have read the same article (s) i did and can help me re find them

I read somewhre mighta been nuts n volts pop electronics or pop sci ...

was an article about a 1 guy, who invented a new type of radio transmission, called pulse width radio, NOT not to be confused w/the long avail current pwm stuff or pw stuff of today

it alleged the technology could lead to cool things like hand held radar units , voice radios small sized that would work over large distances and use low power yah sounds great...

next i heard the military was trying to steel his patents and then almost all reference to the work was gone

it's gotta to have been at least 2yrs? no i can't find a trace of it anyplace

anyone remember this 'news' and have any links to anything on the technology i could reference ??

thanks any help appreciated, realize it'a long shot but i hate not finding stuff

You have seized and fixated on a concept I did not generate, ie, that AM broadcast antennas all need to be SELF-resonant, and that their L-D ratio is the way to achieve that. Anyone referencing my statement quoted above in this post, and thinking its does so has problems with reading comprehension.

Why don't you just accept this reality, and move on?

Please see the following URL Page 6,
http://www.mag-inc.com/pdf/cg-01.pdf
note the graph for the toroid, the inductance decreases by 40 percent
going from 2000 gausse to 10 gausse.

Question 1.
I don't know where on that graph the published permeability would set the
inductance. (to clarify--How many gausse is used to measure permeability
and set AL?)
Question 2.
Can anyone take a stab at how many gausse in a typical FT140-43 toroid
with 8 turns on the secondary, and 34 or 35 turns on the primary used on a
flag antenna with a low level signal.

Maybe if we have two points on that graph we can have a real number to
see how much inductance changes from published AL at low gausse.
Mike

PS. interesting how pot cores have very little inductance change with changing gausse.

> PS Thinking about a Flag antenna, which has a small output signal.

Mike,

I think you are focusing on non-issues and not consider things that are really important.

First, I would not use a 43 core on a low frequency receive antenna. This is especially true with an ungrounded antenna that has exceptionally low signal output, like a Flag.

There are very few antennas in the world that are perfectly UNbalanced or perfectly balanced. Even what we consider an unbalanced antenna can cause feed system problems. When the antenna has very low signal output yet occupies a large spatial area, you are especially looking at problems.

The flag has low common mode impedance, and fairly high differential mode impedance. It is neither balaunced nor unbalanced, it is in that soupy world of something that requires equal and opposite currents at the feed without perfect voltage balance. It is not a balanced antenna, and not an unbalanced antenna.

When that is combined with the very low signal output, you have to pay particular attention to the transformer design.

You really can't use a transmission line transformer because it will not have enough isolation. You need a primary-secondary transformer with isolated and slightly seperated windings. You really don't want a material that requires 30 or 40 turns, because extra wire will increase stray capacitance from primary to secondary.

You almost certainly want to move into a binocular core with fairly high permeability at the lowest frequency, like a 73 material. Unless you have a few volts of RF from a closeby station, flux density is not an issue.

You want to keep primary/secondary capacitance down near a dozen pF or less if possible, and have NO direct path for common mode currents.

I gave a presentation on "How Ham Radio Can Help You in an Emergency"
to 70 Emergency Management types last week, and the windows in the
building which hosted the meeting were NOT open-able (so I "made do"
with an inside VHF antenna and didn't even try to demonstrate HF).

But in emergency/expedient situations, it would be really handy if one
could pass at HF, say, 100 watts of RF energy through a window (I
visualize some foil strips and an inductor or two to "tune out" the
capacitance) to an external antenna.

I've been told that the April, 1989, issue of Ham Radio magazine carried
an article "Easy antenna access for urban apartment dwellers" (for 15
meters) by Bryan Bergeron, NU1N, starting on page 18.

I'd sure like to read that article; can anyone send me a copy?

Brandnew radio and transmitters massageboard

After making the sw pirates group and the radio and transmitters group and not to forget the sw pirates forum a new forum is launched. a huge forum related to building radio, transmitters, ham and ameteur radio and so on, tip and moderators are very welcome, thes board needs promotion so webmasters, do your thing. any halp or placed URL's are welcome
http://forum.alfalima.net/

geheel nieuw, een radio , zender en amateur radio forum, ook voor hulp bij je amateur opleiding,
tips, idee's en moderators zeer welkom

Reality? Now there's a cornpone clichï¿½.

It should take little imagination (dull intelligence rather), once
reading the topic line these postings fall under, to accept the thread
of continuity has been about
1. Loads in
2. very short antennas whose
3. height has been expressed in degrees when
4. resonant.

There is absolutely no difference in outcome, be it an AM antenna, or
a Hamstick in the back yard.

In an emergency I'd say... uh... just leave the window open? :-)

Over on eHam.net there's a recent article on building yourself a simple rectangular wooden panel to stick in the frame of an (open) window. You then just drive holes in the panel as needed to run cables, etc. I've even seen people who didn't have, e.g., a drill or jigsaw do the same thing using a thick-ish chunk of stiff foam (insulation material or even presentation poster board) and an X-acto knife.

But be sure to bring a hefty brick along to create the opening in the first
place :)

The OP's dilema was that the window COULD NOT open, and therefore some
way to pass RF through glass would have been Useful.

What I have done is plan ahead by drilling two small holes in the glass
and plugging them with nylon screws when not in use. That works best
on the first floor. :-)

You'd have better luck with HF than VHF or UHF making it through any solid object. I have used a homebrew mag loop in a hotel room on several ocassions with some luck..on 20 and 40.

I have a 40m dipole in my attic, and I runn less than 5w HF most of the time and I have WAS on several ocassions, I try to WAS every year.

A lot of modern buildings have glass windows which not only cannot be
opened, but which have a "low-E" (low thermal emission) coating on the
glass. This is (I believe) a very thin layer of vapor-deposited
metal.

Its RF attenuation is considerable. Some years ago, we had our house
windows (1960s-era glass) replaced with new ones using a low-E-coated
glass. A previously-workable signal path for 802.11 signals, which
got to the back of the house from an access point in the garage by
going through the garage door and a couple of exterior windows,
suddently became quite unusable - I had to install an additional
access point to cover that part of the house.

The more obviously shaded or reflective the glass, the more of a
problem for RF transmission or coupling this stuff is likely to present.

>

Hi Tom,
Thanks for your input, When I wrote the above I couldn't remember what people were using on there flags so I went to one site and just copied what that site said, maybe it was a misprint and should have said 73.
I used a 3F3 4229 pot core with 3 turns and 13 turns
on my flag, I cut a styrofoam clamshell to go between the sec and pri to limit capacitance. I also put a grounded electrostatic shield between windings.
I was happy with my nulls, (whatever that means;-) but wonder how efficient my transformer was.

My questions still stand,
Question 1
How many gausse is used to measure permeability and set AL?
Question 2.
Can anyone take a stab at how many gausse in a typical FT140-43 toroid with 8 turns on the secondary, and 34 or 35 turns on the primary used on a flag antenna with a low level signal.
On the second question the material can be modified to reflect the material and turns as needed.
Thanks
Mike

I can just see me now:
* Drive to the High-n-Mighty Hotel where I'm to provide communications
for the Red Cross (or Salvation Army) shelter
* Ask the desk clerk for someone to help me carry my sledgehammer and
other stuff in my grab-n-go kit to the shelter
* Walk into shelter where x-hundred shelterees are fast asleep
* Take sledgehammer and bash a hole through a window
* ....

Nope, that's just not gonna work!

Even in an emergency situation, I just don't think it would be a good idea to string some kind of an antenna above the heads of shelterees and then start soaking them with RF, especially depending on the HF frequency in use. In fact, I suspect the FCC's RF-exposure regulations would frown on one doing so!

> Can anyone take a stab at how many gausse in a typical FT140-43 toroid
> with 8 turns on the secondary, and 34 or 35 turns on the primary used on a
> flag antenna with a low level signal.

I won't bother to calculate it because the change in permeability would
be so small you wouldn't be able to measure it. This is a non-problem;
you're wasting your time worrying about it.

> On the second question the material can be modified to reflect the material
> and turns as needed.

If your circuit is sensitive to a change in a few parts per million of
permeability, it has serious problems. The permeability will change
several orders of magnitude more than that with modest changes in
temperature.

Some of the third party replacement antennas were made with military
surplus RG62, and had hand soldered motorola plugs instead of the OEM
crimped plugs. I cut up a lot of old antenna cables and stripped the
copper braid to use as solder wick by dipping it into liquid rosin. Some
had the plastic spacer for the center conductor, but most didn't. Some
weeks we replaced a half dozen car radio antennas, so I always had
plenty of copper braid at hand. years later I worked for a CATV company
repairing converters. The braid from the control cables was a little
under 1/8" when it was pulled tight and flattened by pulling it around
the blade of a screwdriver.

If a transceiver has an in built automatic antenna tuning and matching unit, is there any point in measuring the VSWR as a way of ascertaining its performance?

Obviously this would be measured with a thru line meter which would be placed in the feeder system. However, I have been thinking and it would appear that the tuning and matching unit would become part of the antennas impedance (its late and I hope that makes sense).

The reason I ask is because I am trying to find out how well certain transceivers will perform with antennas which are designed for different systems.

483. DELTA LOOP antenna calculator now work with MMANA

Good morning,

I'am happy to tell you that the delta loop antenna calculator
http://www.antenna-street.com/delta-loop-1en.php

can now generate automatiquely the .maa file from your values.

It is operationnal for each delta loop on 10-11 meters band and from 2 to 6
elements.

This will be online in few hours and hope that MMANA users could give their
opinion.

best regards

oli

My EZNEC data posting proves that EZNEC correctly predicts the
differences in the traveling wave current and the standing wave
current. I'm building a new web page around those results. I have
graphed the EZNEC results and they are available at:

http://www.qsl.net/w5dxp/travstnd.GIF

Please note that the traveling wave magnitude looks like the
standing wave phase and the traveling wave phase looks like the
standing wave magnitude. Anyone who maintains that there is no
difference between a traveling wave current and a standing wave
current should take a long close look.

The corresponding EZNEC files are available at:

http://www.qsl.net/w5dxp/TravWave.EZ
http://www.qsl.net/w5dxp/StndWave.EZ

NOPE! The VSWR in the line = The VSWR in the line = The VSWR in the line = The VSWR in the line. The internal tuner does absolutely nothing [NOTHING] to the VSWR in the line.

The internal tuner will make the radio 'happy' within it's tuning range, but it does NOTHING about the VSWR in the line!

To elaborate just a bit on Dave's comment, remember that the VSWR is
determined only by the LOAD (antenna) impedance and the LINE
characteristic impedance. The source (transmitter) impedance does not
enter into the determination of VSWR.

One way tuners are tested is with dummy loads of various resistances
(and/or reactances). QST published some articles on this a few years ago.

Good luck.

Thomas,

Belden made a product called "Shielded Perm-ohm" 300 ohm shielded twin
lead. It apparently still exists, but not with that name. Go to
http://www.fairradio.com/wirean.htm and search for it. The
product is now called "City Color," according to that web page.

Some years ago I used it to pass perfect TV signals through a 15-foot
conduit
out of my attic . (An earlier attempt with regular twinlead was a
disaster.) I
believe the shielded twin lead has slightly less loss than coax.

Ok, So I'll use the figure of 1 gausse as where permeability is measured and
from there I can assume the inductance increases 40 percent at 2000 gausse
for the toroid specified on the Magnetics webpage. The only info I have is
from
Ferroxcube Soft Ferrites and accessories 2000 data book, and it simply says
"The initial permeabilty is measured------ at a very low field strength."

I'm not worrying, just curious, since I've been using a large potcore to
deliver microwatts that at one time I used at near a kilowatt. Just
wondered
if we were losing some low frequency response because of a change in
permeability. It seems as though the permeabilty measurement is made nearer
the power levels of our receive antenna signals.

Source record: 61534

I'm renting a basement suite and have an Icom 706mkII & MFJ-949E antenna tuner, and I need a better HF antenna arrangement than I already have (without going to a tower, hi). I would like to run a balanced feedline from the tuner to the feedpoint but the feedline has to go from my shack to where the feedpoint is, and that involves crossing a cement path --- in other words, because the feedline has to lie on top of cement it can't really be anything other than coax. I've put tons of pictures and explanations and diagrams on my webspace at: "http://members.shaw.ca/cyberhun/ham.htm"
--- please take a look and if you have any ideas let me know. I'm somewhat at a loss as to where to go with it now. I'm thinking the only way to significantly improve on the current arrangement is to run a feedline up from my shack, to the south-west corner of the roof. This would eliminate the need for coax (across the path) and then run radiating elements from the feedpoint to the south-west corner of the yard, and from the feedpoint to the south-east corner of the roof, maybe?

New program LINE_ZIN, for given frequency and load impedance, for
balanced-twin lines, calculates -

Impedance Zo
Input impedance, R+jX
Attenuation, dB
Power efficiency %
Loss with standing waves, dB
Reflection coefficient
Angle of refl.coeff.
SWR at load end
SWR at input end

Input data can be varied in small increments from the keyboard to
observe how a line behaves. Practical and educational.

Download program LINE_ZIN (40 K-bytes) in a few seconds from website
below and run imediately.

Message-ID: <JVkZf.64$LZ5.1@fe08.lga>
Source record: 61535

W8JI and other unbelievers that antenna and loading coils can not be expressed in electrical degrees, can find another example in ON4UN's Low Band DXing book, 4th edition, page 9-47, Fig 9-58, showing loaded vertical with mast being 40 deg. 59.6 ft. long, loading coil of 144 uH taking (replacing radiator of) 40 deg and whip of 10 deg and 14.9 ft long, for overall 90 deg electrical and quarter wave resonant system.
Soooo, to anyone outside of "equal current worshippers" it is obvious that coil is replacing 40 deg worth of radiator and it would drop equivalent amount of current across the coil that corresponds to the length of radiator that coil replaces, because rest of the "straight" radiator FORCES IT TO DO - because of standing wave and current.

Such a heresy!
Theeere is your sign!

That is not correct Yuri.

Anything from a pure inductance to a very poor distributed inductor
(like a linear loading or stub) can be used and all would have
different characteristics.

A pure inductance would have no current difference at each end. A good
compact inductor would have negligible current difference at each end,
only a long straight wire would act like the "missing antenna".

One way to prove the coil does not replace missing length is to simply
move the coil to a new location in a fixed height antenna. If the coil
looked like 40 degrees, it would resonate the antenna no matter where
it was installed.

Hi Yuri,

So obvious that you cannot express the accuracy necessary to resolve the "big picture." So obvious you cannot express the actual efficiency of having the coil there, or not having the coil there. So obvious that it is 40 degrees, that the previously unknown accuracy allows that to slip between 16.4 degrees and 63.6 degrees. So obvious that if you choose just the right number, then you can resonate on three bands with one coil. So obvious: who needs an antenna?

What is not obvious is the name of your religion.

> for overall 90 deg electrical and quarter wave resonant system.

Hence my recent correspondence has anticipated just this claim - but then that was as easy as shooting hunting partners in the face.

You could make up a section of shielded balanced line, to get the feed
across the cement without having it couple messily into the ground.

A shielded balanced line can be made from two equal-length runs of
coax cable. RG-6 would work; aluminum-jacketed cable-TV hardline
might be even better from an electrical standpoint although its
rigidity might be inconvenient. Connect the shields/braids of the two
sections of coax together at each end, use the center conductors
to carry the signal, and fasten the two coaxes together in some
convenient fashion (an occasional nylon wire-tie would do, I believe).

The impedance of such a line will be twice that of the individual
pieces of coax - i.e. 150 ohms if you use RG-6. No need to worry
about matching it to the rest of the balanced feedline. You can use
300 or 450 or 600-ohm (nominal) balanced line where convenient, to
keep the losses as low as practical, and this 150-ohm shielded
balanced pair where necessary. The losses should be acceptable, and
will certainly be less than if you plumbed the whole distance with 50-
or 75-ohm coax.

I do not have the article but one solution that was proposed and tried worked great. Use tinfoin and rubber glue, cut the tin foil to fit the glass. Apply rubber glue to hold the foil to each side of the glass, Thickness of teh glass is not important. In my case I used the metal frame of the glass to carry the gound signal through the window frame. I then used an antenna tuner to adjust out the capacitor I just created. Worked great, no drilling no running coax in and out so I can close the window etc.

Another 'speriment occured to me, for those who think the coil current MUST be different at the two ends by the amount corresponding to the antenna section it replaces: try making the antenna diameter large compared with the coil diameter, say two to four times the coil diameter, while maintaining the same lengths, and see what happens. I suppose you'll have to adjust the inductance of the coil, but keep its diameter and length the same. If the current at the ends of the coil remains nominally the same as with a thin antenna, then I'll say you're onto something. If on the other hand, the current becomes much more similar at the two ends of the coil, that will be evidence of a different effect--in fact the effect that I expect is actually accounting for the difference.

Perhaps someone would like to try that in NEC2 or NEC4 and share the results, if nobody is actually up to building the antenna and measuring things.

Cheers,
Tom

Source record: 61545

Of course loading coils can be expressed in electrical degrees. But extrapolating this to mean that a loading coil has the same properties as an antenna with the same number of "degrees" has no justification.

Yuri's theory was shown to be false not only by many of the good technical arguments given here in this thread, but also by a careful measurement I made over a year ago. I built a 33 foot high vertical and loaded it at the bottom with a toroidal inductor to resonate it at 3.8 MHz. The coil "replaced" 33.4 electrical degrees of antenna. Yuri's theory predicts that the current at the top of the inductor should be 16.5% less than that at the bottom, with a phase shift of 33.4 degrees. What I measured was a current drop of 5.4% and no measurable phase shift across the inductor. Both the description of the setup and the detailed results were posted on this newsgroup on Nov. 11, 2003, with the subject title "Re: Current in antenna loading coils controversy - new measurement". Anyone can find those postings with groups.google.com.

Yuri's response, also on Nov. 11, 2003 was to complain about my methodology, declare that he was still right, and state "I will measure things myself, try to verify previous measurements and then come up with conclusions and 'theory'."

On Nov. 12, 2003, he posted: "I will be making snap-on current probe, which will make it easier to slide along the element and observe the current without the disturbance to the antenna and will be a bit different over the thermocouple meters. Just need a bit more time."

Well, it's been over a year now, and all I've seen is the same unsupported theory with no evidence to contradict the contrary evidence which has been presented.

When a belief stays fixed in spite of both contradictory solid theory and measurements, it fits into the category of religion, not science. So it's appropriate that Yuri speaks in terms of an explanation being a "heresy". What's next, "good" and "evil" theories?

I'm afraid that the proponents of the alternative theories aren't subject to either modeling or measurement results. There's already ample theoretical, modeling, and measurement evidence to show that the theory is faulty; further efforts would be a waste of time.

It certainly *is* possible to make a correct analysis of a short coil-loaded antenna in terms of forward, reflected and standing waves of current.

My objections are only about errors in Cecil's specific attempt to do it.

This particular problem is a small hole in our jigsaw puzzle of human knowledge. It would certainly be worthwhile to craft a new piece, and to have the satisfaction seeing it fit exactly into place.

But jigsaw puzzles have unbreakable rules: a new piece must fit EXACTLY into the gap that it fills; and everywhere around its edges, the picture MUST join up EXACTLY. If it fails to fit exactly and in every detail, then it isn't the right piece.

All the surrounding pieces of existing knowledge about antenna engineering fit neatly together to make a solid picture. We can see the big picture, and that we're only trying to fill a very small gap.

That big picture is made up from only a very few primary colors. They can blend together to give infinite hues and subtleties, but everything comes from mixing those same few primary colors which DO NOT CHANGE.

The 'primary colors' of antenna engineering are a few fundamental physical facts that DO NOT CHANGE from one piece of the puzzle to the next. (Out at the far edges of the puzzle, the advances of 20th-century physics have shown that classical physics is part of an even bigger picture than we'd imagined - but in doing so they have confirmed where the rules of classical physics still CAN be applied. That includes the whole of electrical and electronic engineering, except for what happens inside semiconductor devices. Regarding antennas, Einstein's equations include and clarify Maxwell's equations, and quantify the margins of error in this area of classical physics. This confirms that antenna engineering indeed CAN be completely and accurately understood using classical physics, because the margins of error are too small to affect any practical observations.)

Returning to this particular gap in the picture of antenna engineering, concerning short loaded antennas, we can see that it's only a small gap. It is surrounded by large areas of existing knowledge that interlock solidly and completely. That means we can be confident there will be nothing different or special happening inside that gap.

When trying to fill any gap in our existing knowledge, that piece of advance information - that the same fundamentals will apply - is a tremendous help. Or it should be... the trouble starts when someone tries to ignore that fact, or worse still, tries to fight it.

It is also important to note that there are already several other ways of thinking about loaded antennas that DO fit perfectly into the puzzle. There are many alternative ways to think about any particular piece, and as long as they fit with reality all around them, they are interchangeable.

Cecil wants to try a method based on forward, reflected and standing waves, and that's just fine. As i said, I'm sure it can be done. The existing knowledge that such a theory must fit includes: what travelling and standing waves are; what electric current is; what inductance does; how real-life coils are different; and how things change when circuits become physically large enough to make electromagnetic coupling important (so we begin to call them antennas).

But Cecil's new piece for the puzzle uses new and special definitions and properties for electric current, inductance, and travelling and standing waves - they are not the same as in all the surrounding pieces. To me, that is absolute proof that his new piece doesn't fit. He has bent the rules to make it resemble the correct shape, but the colors don't match.

Exactly why it doesn't fit remains a matter for debate. But I am fundamentally sure of the *fact* that it doesn't.

(Will be away from the screen now until about Tuesday.)

Ralph Mowery wrote:
>
> I see that you have reached your limit. Check the data and repost with
> the correct ammount of electrons, protrons and neutrons.
Ralph,
check the periodic table again.
helium is a NOBLE gas (it exists on the far right hand column of the
periodic table because of its non-reactiveness).

Helium is Element 2.
atomic weight: 4.002602
Number of Protons/Electrons: 2
Number of Neutrons: 2

information from this link <
http://www.webelements.com/webelements/elements/text/He/key.html >
is as follows:

"Helium is one of the so-called noble gases. Helium gas is unreactive,
colourless, and odourless. Helium is available in pressurised tanks.
Elemental helium is a colourless odourless monoatomic gas. Helium is the
second most abundant element in the universe after hydrogen. a particles
are doubly ionised helium atoms, He2+.
Helium is used in lighter than air balloons and while heavier than hydrogen,
is far safer since helium does not burn. Speaking after breathing an
atmosphere rich in helium results in a squeaky voice (don't try it!).
Isolation
Here is a brief summary of the isolation of helium.
There is very little helium on earth as nearly all present during and
immediately after the earth's formation has long since been lost as it is
so light. Just about all the helium remaining on the planet is the result
of radioactive decay. While there is some helium in the atmosphere,
currently its isolation from that source by liquefaction and separation of
air is not normally economic. This is bacause it is easier, and cheaper, to
isolate the gas from certain natural gases. Concentrations of helium in
natural gas in the USA are as high as 7% and other good sources include
natural gas from some sources in Poland. It is isolable from these gases by
liquefaction and separation of from the natural gas. This would not
normally be carried out in the laboratory and helium is available
commercially in cylinders under pressure."

note the part where it says:
"There is very little helium on earth as nearly all present during and
immediately after the earth's formation has long since been lost as it is
so light. Just about all the helium remaining on the planet is the result

of radioactive decay."

would you care to explain that?????

conversely, Hydrogen is:
Element 1
atomic weight: 1.00794
Number of Protons/Electrons: 1
Number of Neutrons: 0

hydrogen is also known to have *at least* 5 known isotopes (all unstable and
all prone to radioactive decay).

lastly, as for your personal dig at my signature, me thinks thou doth
protest too much!

there was no reference to diatomic structures that I could discern. :(
the problem with hydrogen is that it likes to either react with elements
that are stable in diatomic form (such as Oxygen) or other elements that
may have an excess of electron valence values (free electrons). Being that
Hydrogen is a proton with an electron in orbit, the + charge of the proton
will naturally tend to repel other elements of an equal charge, including
itself.

>
> However, you have the better point: Hydrogen spells danger. Hydrogen,
> Hindenburg,...If being a survivor means being a pansy...cool.

the one advantage of Hydrogen is that it is very easy to produce planet side
(add a little electricity, 2 probes of the same metal and enough water and
there you go).

Helium is rather harder to get here on earth. because of the processes
involved, it tends to be pricey.

ok,
the original poster did not clarify as to which isotope of hydrogen was being used. H2 is a stable isotope (and yeah, I do stand corrected on that point). Still, the energies required to get 2 protons and 2 electrons to get along are fairly high. Hydrogen (H not 1 or 2 or bloody 3...) is very small (smaller than helium) and will tend to slip through most materials (except for possibly the extremely dense materials such as Polonium).

perhaps in the future, we should be a bit more concise about things like this..... now I know that diatomic hydrogen is fairly common in nature (as in H2O, CH2 and a few others). I would have to ask a question of some folks over at ASU to see what they use for high atmosphere balloons.

Perhaps.

In an emergency situation though, you do what you need to do and try not to let the regulations keep you from saving lives and/or property..while still keeping the regs in mind.

When I use my portable mag loop for 20 and 40, from my hotel room, I try to place it outside my room...but that hasn't always been possible. At my low power I would have to guess the RF I'm bathing in should only be slightly more harmful than the X rays leaking out of my cheap "Made in Turdistan" TV set. I certainly wouldn't attempt using this setup with much more than a few watts of power.

As for my attic dipoles, I have never tried to measure the exposure level in my home. I'll check in to that..but again, at 5w or less it can't be too dangerous.

The coil occupies a different number of degrees depending upon
its location in the standing wave environment. That's why the
resonant frequency of a bugcatcher system increases as the
coil is moved up from the base. In a one wavelength standing
wave system, if the coil is installed at a node, the currents
at each end of the coil will be ~180 out of phase, i.e. the
two currenets *appear* to be flowing in opposite directions at
the same time.

To the best of my knowledge, nobody believes that. The coil
is much more efficient at the loading function than is the
straight wire from which it is made. That's why inductive
loading is more efficient than fractal antennas or other
types of linear loading.

WRONG, read below, it's the required inductance/impedance and fixed
"missing" degrees that need replacement.

> 73 Tom
>

Another big WRONGO Tom!
As we go deeper into the discussion and "arguments" from "unbelievers" and thanks to NM5K posting, about how fixed coil acts different, replaces different amount of degrees, it hit me that the reason is the impedance presented by the antenna (the straight part) radiator at the coil insertion point. Using just as example, radiator having 90 degrees at the resonance, with 50 degrees of whip and coil "replacing" 40 degrees in the said example from the book.

You agree that impedance along the radiator changes, being low at the bottom, around tens of ohms, to being high at the top, around thousands of ohms. Now you place the loading coil along the radiator, one extreme being at the bottom, low impedance point - we know in order to maintain the resonance of say 13 ft high (long) radiator (90 electrical degrees at RESONANCE) the coil has a fewer turns, it's impedance is lower (as required by the lower impedance at the bottom end of the antenna), and current drop would relatively be small as W7EL proved and everybody knows.

Now you move that coil say half way up the must, to higher impedance point at the antenna, and that coil now, in order to maintain the "match" has to have higher impedance, more turns and will exhibit MORE current drop across it, while replacing THE SAME NUMBER OF "missing" DEGREES AT THE RADIATOR. Assuming that our goal is to stay with the same physical length of the whip (which we do) and maintaining 90 degrees of resonant radiator. So the radiator stays 50 degrees ()+50, 10+40, 20+30, 30+20, 40 + 10) long and coil replaces the same "missing" 40 degrees.

Same if you move the coil higher, higher antenna impedance point, more turns (inductance) required, more current drop exhibited, coil "replacing" THE SAME NUMBER OF 40 DEGREES. It needs more turns, but again, the coil's behavior is dictated by the impedance of the RADIATOR (standing waves) at the insertion point, dictating the inductance, number of turns of the coil in order to maintain the number of degrees, in order to maintain the resonance (90 degrees) of the radiator.

In order to "overturn" this "Yuri's Theory" you would have to deny that resonant antenna has varying current across its radiator (wire) - to deny that current drops from the base to the tip.
You would have to deny that coil in the RF circuit has varying impedance dependant on the number of turns and inductance and frequency.
Deny that in order to maintain the resonant frequency of shortened radiator of the same physical length, you need to use coils of varying amount of turns depending on its insertion point along the radiator (less on the bottom, more closer to the top).

That behavior of the coil is "FORCED" by the remaining "wires" in the radiator, in standing wave environment as Cecil is trying to get through with help of Kraus and others. So if the antenna is 50 degrees long and we want to maintain the resonance, the coil will replace (has to) the same 40 degrees regardless where it is placed, but its inductance and impedance will vary, depending on the impedance of the insertion point at the radiator. (Makes also sense - more turns - more current drop, RF choke effect. We are still talking RF current in standing wave antenna, not DC.)

So the drop of RF current across the coil, depending on its position in the resonant quarter wave radiator can be from little at the base, to significant closer to the top, dependent on the position, insertion point, impedance of the radiator. This is much more significant cause of current drop across the coil that any "radiation or capacitance to the environment" (Tom's trying to "twist out of it") as is demonstrated by our arguments.
So if we look at the fixed length of radiator and try to bring it to resonance with coils, placed at different locations along the radiator, we are replacing the SAME amount of electrical degrees, but depending on the required impedance, then the number of turns, or inductance has to be adjusted to conform. That jives what you and everybody knows and keep saying.
So it is not the fixed inductance, (missing) length of wire in the coil, or same number of turns that replaces degrees of "missing" radiator, but the REQUIRED INDUCTANCE/IMPEDANCE and corresponding number of turns.

I hope this makes it little bit more clear and shuts down another WRONGOOO that keeps popping up. Just measure it, stick it (properly defined) in EZNEC - IT IS ALL THERE, for everyone to see.

So then if the standing wave causes drop of the RF current across the solid wire of the antenna, it also causes the drop of current across the loading coil, proportional to the amount of electrical degrees of radiator that coil "replaces", magnitude being dependent on the impedance and inductance required by the insertion point impedance along the radiator. (Almost sounds like "Yuri's Law" :-)

I would like to thank NM5K for bringing it up and making me to understand what the "problem" and proof is. It made me realize what role impedance of the inductor plays in the STANDING WAVE antenna/circuit.
Sooo! The coil can and have RF current variation, drop across it, just like piece of wire can, when in standing wave (antenna) environment. It is the major cause and not the whatever capacitance etc. You wanna call it K3BU's theory, I would be honored, but I do not claim any "ownership", many others before me showed that, directly or indirectly, including John Kraus, W8JK.

I promise to do that article and series of experiments showing close correlation between measurements and proper modeling in EZNEC, just give me couple of weeks. I hope it will show and educate those willing to open their minds, and those "flat Earthers" can do what they choose to (look silly).
I hope I made it more clear. I don't know how else I (we) can get it through!

Soooo, but, but, but.... what?

Yuri Blanarovich, K3BU.us

I apologize to technical language purists for any clumsy wordiness' I may be guilty of.

==========
Might be OK for single - ,but NOT for double glazed windows.

A solution for HF 'might' be an inductive coupler/matching unit , with
half of it including an inductor on the outside with the other inductor
and 'tuning bits' inside .Both inductors 'in-line' for best possible
coupling. If an outside variable capacitor is to be used ,its shaft
could possibly be magnetically coupled with a manipulator fitted inside
,using strong magnets .
Home-brewing Ham Radio equipment is and remains an interesting
ideas-provoking activity .

> Of course loading coils can be expressed in electrical degrees. But
> extrapolating this to mean that a loading coil has the same properties
> as an antenna with the same number of "degrees" has no justification.

I haven't heard anybody make that assertion in years. Coils
occupy whatever number of degrees that they occupy. The
technical fact is that standing wave current phase cannot be
used as the method of measuring the number of degrees. The
graphic at http://www.travstnd.GIF shows why. The standing
wave current phase is unchanging unless the monopole length
goes over 1/4WL.

> What I measured was a current drop of 5.4% and no measurable phase shift
> across the inductor.

But Roy, you used standing wave current phase to try to measure
the phase shift across the inductor. The standing wave current
phase is known to be unchanging in a wire. Why would you expect
it to change through a coil? As Gene Fuller says, the only phase
information in the standing wave current is in the magnitude
measurement. If the magnitude changed by 5.4%, the phase shift
was roughly arc-cos(1 - 0.054) = arc-cos(0.946) = ~19 degrees.

Please take a look at what EZNEC says about the standing wave
phase shift in 1/4WL of wire at:

http://www.qsl.net/w5dxp/travstnd.GIF

and please tell us again how you used a current with an unchanging
flat phase to try to measure the phase shift through a coil.

> Well, it's been over a year now, and all I've seen is the same
> unsupported theory with no evidence to contradict the contrary evidence
> which has been presented.

No evidence? Even EZNEC says one cannot use standing wave current
phase to measure phase shift. I told you that fact over a year ago.
Your phase measurement methods are just as invalid today as they
were a year ago.

> When a belief stays fixed in spite of both contradictory solid theory
> and measurements, it fits into the category of religion, not science.

You are talking about your religious method of using the unchanging
standing wave current phase to try to measure a phase shift. EZNEC
says that is not a valid approach.

Regarding the cos(kz)*cos(wt) term in a standing wave:

> Gene Fuller, W4SZ wrote:

Roy,
please see my other posting, otherwise, I really promise to do the step by step article, which will try to explain, correlate real life measurements and modeling and present the comprehensive case of current being different across antenna loading coils. Will do that with cooperation of other "defenders" that contributed to "our" cause. There is no point of going back and forth on tangents. We will measure, show the reality and then apply some theory, explanation and summary of what is going on.
I hope it will correct misconceptions, provide better understanding and benefit in proper modeling and design of loaded antenna elements and systems.
Otherwise, I think we have reached point, when it is pointless to go around in circles and argue that what IS, CAN'T BE, because.....

I fail to see what you are all arguing about.

A length of transmission line, or a coil insofar as it behaves as a length of transmission line, has a fixed number of degrees of phase shift which depends only on frequency.

You can shift it about, put it in a different antenna, do what you like with it, but, at the same frequency, it will always have the same number of degrees.

Now stop this childish argument before I bang your heads together.

Referee Reg.

I haven't heard anybody make that assertion in years. Coils
occupy whatever number of degrees that they occupy. The
technical fact is that standing wave current phase cannot be
used as the method of measuring the number of degrees. The
graphic at http://www.travstnd.GIF shows why. The standing
wave current phase is unchanging unless the monopole length
goes over 1/4WL.

Here's what you said earlier:
>I said that Cecil's phase measurements agree with EZNEC (and generally
>accepted theory) -- there should be almost no phase shift in the current
>along the wire.

If there's no phase shift along the wire, why would you expect to
measure phase shift through a coil. After you made the above
posting, I thought you understood that - but apparently not.

I told you that your phase shift measurement was invalid a year ago
and it is just as invalid now as it was then. There is no phase information
contained in standing wave current phase. This is the basic misconception
that has resulted in invalid data reported by you.

> What I measured was a current drop of 5.4% and no measurable phase shift
> across the inductor.

But Roy, you used standing wave current phase to try to measure
the phase shift across the inductor. The standing wave current
phase is known to be unchanging in a wire. Why would you expect
it to change through a coil? As Gene Fuller says, the only phase
information in the standing wave current is in the magnitude
measurement. If the magnitude changed by 5.4%, the phase shift
was roughly arc-cos(1 - 0.054) = arc-cos(0.946) = ~19 degrees.

Please take a look at what EZNEC says about the standing wave
phase shift in 1/4WL of wire at:

http://www.qsl.net/w5dxp/travstnd.GIF

and please tell us again how you used a current with an unchanging
flat phase to try to measure the phase shift through a coil.

> Well, it's been over a year now, and all I've seen is the same
> unsupported theory with no evidence to contradict the contrary evidence
> which has been presented.

No evidence? Even EZNEC says one cannot use standing wave current
phase to measure phase shift. I told you that fact over a year ago.
Your phase measurement methods are just as invalid today as they
were a year ago.

> When a belief stays fixed in spite of both contradictory solid theory
> and measurements, it fits into the category of religion, not science.

You are talking about your religious method of using the unchanging
standing wave current phase to try to measure a phase shift. EZNEC
says that is not a valid approach. Even Gene Fuller says there is zero
phase information in standing wave current wave and he generally
agrees with you.

Regarding the cos(kz)*cos(wt) term in a standing wave:

Roy, it is you who are ignoring the results of EZNEC. EZNEC proves
that one cannot use standing wave current phase to measure the phase
shift through a wire, much less through a coil. To see why, take a look at:

http://www.qsl.net/w5dxp/travstnd.GIF

The standing wave current is absolutely FLAT. It cannot be used for
any valid measurement.

The real question is: Is it possible for Ian White to make a mistake?
If the answer is, 'yes', then it possibly could be your mistake and
not mine. Or both of us could be making mistakes.

> But jigsaw puzzles have unbreakable rules: a new piece must fit EXACTLY
> into the gap that it fills; and everywhere around its edges, the picture

> then it isn't the right piece.

But what if somebody mutilated one of the pieces? That final piece is
not going to fit whether it is correct or not. That's what you have done -
mutilate one of the pieces so the final piece doesn't fit.

> Returning to this particular gap in the picture of antenna engineering,
> concerning short loaded antennas, we can see that it's only a small gap.

But some of the concepts in that large area of existing "knowledge" are
false. I know what your misconception is. If you will use your ears
instead of your mouth, you could understand what that misconception
really is.

> Cecil wants to try a method based on forward, reflected and standing
> waves, and that's just fine.

Not only is it a fine way to deal with the problem, its use exposes your
misconception. Wouldn't you like to correct that misconception?

> But Cecil's new piece for the puzzle uses new and special definitions
> and properties for electric current, inductance, and travelling and
> standing waves - they are not the same as in all the surrounding pieces.
> To me, that is absolute proof that his new piece doesn't fit.

All it means is that you mutilated one of the pieces. Fix your mutilated
piece and my piece will fit.

> Exactly why it doesn't fit remains a matter for debate. But I am
> fundamentally sure of the *fact* that it doesn't.

I agree it doesn't fit but the reason it doesn't fit is your mutilated
piece installed previously.

The mutilated piece is the nature of standing wave current and I know exactly how it was mutilated. If you are willing to discuss that narrow issue from a purely technical standpoint, I can show you how to fix your piece so that my piece will fit nicely just as it should.

Yuri, I think it is obvious that some people are suffering from
misconceptions.

The misconception that the "experts" are suffering from has *nothing* to do
with coils. That's the reason the coil discussion has gone in circles. There
may not be anything wrong with the coil concepts.

The misconception is about standing wave current VS traveling wave current.
The "experts" have asserted that "current is current" and that standing wave
current is the same as traveling wave current even though they have
different
equations. Even EZNEC recognizes the difference between standing wave
current and traveling wave current. I took a quarter wavelength of wire and
drove it as a standing wave wire and as a traveling wave wire. The piece
of wire was identical in both cases. I've posted the EZNEC results a
number of times and none of the "experts" have responded. Here they are
again: The corresponding EZNEC files are available at:

http://www.qsl.net/w5dxp/TravWave.EZ I(x,t)=Io*cos(kx+wt)
http://www.qsl.net/w5dxp/StndWave.EZ I(x,t)==Io*cos(kx)*cos(wt)

% along current in current in
wire #2 TravWave.EZ StndWave.EZ

0.28% 0.9998 at -0.99 deg 0.9996 at 0 deg
9.72% 0.9983 at -9.39 deg 0.9843 at -0.03 deg
19.7% 0.9969 at -18.23 deg 0.9454 at -0.05 deg
30.3% 0.9957 at -27.59 deg 0.8843 at -0.06 deg
39.7% 0.9949 at -35.96 deg 0.8023 at -0.08 deg
49.7% 0.9945 at -44.84 deg 0.7014 at -0.09 deg
60.3% 0.9945 at -54.20 deg 0.5840 at -0.09 deg
69.7% 0.9949 at -62.58 deg 0.4528 at -0.10 deg
79.7% 0.9956 at -71.43 deg 0.3110 at -0.11 deg
89.7% 0.9965 at -80.27 deg 0.1616 at -0.11 deg
99.7% 0.9976 at -89.14 deg 0.0061 at -0.11 deg

These values reported by EZNEC are graphed at:

http://www.qsl.net/w5dxp/travstnd.GIF

Their differences are obvious. One might even argue that they are
opposites. The traveling wave magnitude looks like the standing

wave phase. The traveling wave phase looks like the standing wave magnitude. That fits perfectly with Gene Fuller's assertion that there is no phase information in standing wave current phase. The only phase information in the standing wave current is in the magnitude. Once the "experts" realize that is the source of their misconception, everything will fall into place.

Again, it is NOT about coils. It is all about misconceptions involving standing wave current.

No, it is factual. No need to call names or get angry.

It is the stray capacitance from the inductor to the outside world that allows any difference in current. Not the standing waves, not the missing area of antenna.

I can have a fixed antenna and with no change other than the style of coil have anything from nearly immeasurable differences to large differences.

For example if the coil is a very large area single turn, it will behave almost like the "missing degrees" you talk about. If it is a compact inductor and has low capacitance to the outside world compared to the antenna above the coil, it will have very little current difference.

What NM5K posting is that?

A coil is a coil. It doesn't know where you are using it. You teminate it with a certain impedance, it operates the same way.

You can call it "40 degrees" or anything you like, but you better not think it acts like that missing antenna area so far as phase shift or current difference between ends. It doesn't act that way.

If it DID act the way you seem to be saying, a base loaded antenna
would be a terrible antenna. Yet over a good groundplane with a
reasonable inductor design, they can be very good.

> You agree that impedance along the radiator changes, being low at the
> bottom, around tens of ohms, to being high at the top, around thousands of

I never said that. What do you mean by reactance? The X can be very
high but radiation resistance very low even near the open end.

>Now you place the loading coil along the radiator, one extreme being
> at the bottom, low impedance point - we know in order to maintain the

So you admit your "my coil replaces 40 degrees" doesn't work? Or what
are you saying?

> Now you move that coil say half way up the must, to higher impedance point
> at the antenna, and that coil now, in order to maintain the "match" has to
> have higher impedance, more turns and will exhibit MORE current drop across
> it, while replacing THE SAME NUMBER OF "missing" DEGREES AT THE RADIATOR.

So the " 40 degrees" is just a meaningless number. It doesn't mean
anything so far as the coil goes. I'll go along with that.

> Assuming that our goal is to stay with the same physical length of the whip
> (which we do) and maintaining 90 degrees of resonant radiator. So the
> radiator stays 50 degrees ()+50, 10+40, 20+30, 30+20, 40 + 10) long and coil
> replaces the same "missing" 40 degrees.

As long as we both agree it does not have anywhere near the same amount
of current difference from start to finish the same length of antenna
would have, I agree.

If you are claiming the current difference at each end of the coil
relates to electrical degrees it "replaces" and not capacitance from
the coil to the outside world, I disagree.

> Same if you move the coil higher, higher antenna impedance point, more turns
> (inductance) required, more current drop exhibited, coil "replacing" THE

> the insertion point, dictating the inductance, number of turns of the coil
> in order to maintain the number of degrees, in order to maintain the
> resonance (90 degrees) of the radiator.

The only reason why the inductor could have more "current drop" (what a
concept! current doesn't drop.) is because displacement current from
capacitance can be a larger portion of load impedance. The coil, in
effect, it acting a bit like a tiny "hat" and robbingh the whip above
the coil of current. Some displacement current branches off to the

world around the coil, leaving less to travel upwards.

> In order to "overturn" this "Yuri's Theory" you would have to deny that

> bottom, more closer to the top).
> That behavior of the coil is "FORCED" by the remaining "wires" in the
> radiator, in standing wave environment as Cecil is trying to get through
> with help of Kraus and others.

You are free to think what you like, but I don't think Kraus is helping Cecil. While a properly done use of standing waves would work, my opinion is Cecil just has a fixation on it and is trying to change the behavior of the system to match his misapplication of standing waves to the coil.

I can take the VERY SAME radiator, make no change in coil location at all, and change the current ratio at the start of the inductor and end of the inductor ONLY by changing inductor design. This is with the antenna operated on one frequency, with one coil location, and with the feedpoint at X=0 (resonance).

If your theory about standing waves or the "40 degree replacement" theory is correct, I sould not be able to do that. Yet I can.

I can build a loading coil that has almost no current difference across the length, change nothing else but the coil, and wind up with almost anything I like for current difference.

The reason that happens is displacement current and the fields around the coil. It is not a function of standing waves or the "missing area" the coil replaces.

It takes a lot less than three years of name calling and arguing to measure it, assuming people can channel their energy into doing something besides running around talking about people or arguing.

The only reason why the inductor could have more "current drop" (what a
concept! current doesn't drop.) is because displacement current from
capacitance can be a larger portion of load impedance. The coil, in
effect, it acting a bit like a tiny "hat" and robbingh the whip above
the coil of current. Some displacement current branches off to the

world around the coil, leaving less to travel upwards.

> In order to "overturn" this "Yuri's Theory" you would have to deny that

> That behavior of the coil is "FORCED" by the remaining "wires" in the
> radiator, in standing wave environment as Cecil is trying to get through
> with help of Kraus and others.

You are free to think what you like, but I don't think Kraus is helping Cecil. While a properly done use of standing waves would work, my opinion is Cecil just has a fixation on it and is trying to change the behavior of the system to match his misapplication of standing waves to the coil.

I can take the VERY SAME radiator, make no change in coil location at all, and change the current ratio at the start of the inductor and end of the inductor ONLY by changing inductor design. This is with the antenna operated on one frequency, with one coil location, and with the feedpoint at X=0 (resonance).

If your theory about standing waves or the "40 degree replacement" theory is correct, I sould not be able to do that. Yet I can.

I can build a loading coil that has almost no current difference across the length, change nothing else but the coil, and wind up with almost anything I like for current difference.

The reason that happens is displacement current and the fields around the coil. It is not a function of standing waves or the "missing area" the coil replaces.

It takes a lot less than three years of name calling and arguing to measure it, assuming people can channel their energy into doing something besides running around talking about people or arguing.

I wonder if you can still remember ANY of your High School Chemistry or
Physics. H2 isn't an Isotope of anything. An Isotope is a chemically
identical atom that has a different number of NEUTRONS than others
of the same Chemical Element. Whether it is Diatomic, multiatonic,
or singular in nature has NO bearing on if it is an Isotope.
Hydrogen has three isotopes.
Hydrogen = One proton and one electron
Detirium = One proton, one neutron, and one electron
Tritium = One proton, two neutrons and one electron

Me a NitroOrganic Chemist, in a previous life

The "experts" have that same problem, Reg, yet they are using
standing wave current phase to try to measure phase shift
through a coil, a known invalid approach since standing wave
current phase doesn't contain any phase information.

You are using standing wave current to try to prove your concepts
are valid. If you don't take time to understand standing wave current,
you will never correct those misconceptions.

Standing wave current phase contains no phase information. Therefore,
standing wave current phase cannot be used to measure the phase shift
through a wire or a coil.

The only phase information in a standing wave current is in the
magnitude which roughly follows a cosine function distorted by
the fields in the loading coil.

If the current at the bottom of the coil is 1.0 amps and the current
at the top of the coil is 0.7 amps, the phase shift through the coil
is *roughly* arc-cos(0.7) = ~45 degrees. As Gene Fuller says,
there's no phase information in standing wave current phase.
All the phase information is embedded in the magnitude. That's
easy to see from the I(x,t) = Io*cos(kx)*cos(wt) equation for
standing wave current.

It's also easy to see from: http://www.qsl.net/w5dxp/travstnd.GIF
plotted from EZNEC data.

Gene,

Don't hold your breath while waiting for Cecil to agree the NEC engine
he uses to prove you can only calculate current by using reflected
waves does not use reflected waves!

I'm still trying to find out why my meter measures standing wave
current and not "real current", or whatever the heck he is saying.

I just made a QSO with Australia and got a 599 and I only used
standing wave current! Imagine how loud I would have been if I used
real current.

Gene, I don't make fools of the "experts". They do
that to themselves through such statements as
"current is current", implying that standing wave
current is identical to traveling wave current which
you know is NOT the case (thanks for your earlier
posting).

Wouldn't it be better to explain standing wave current
to the "experts" in a private email than attacking me
here for "fooling the experts"? You and I are in
essential agreement. It's the "experts" who use
standing wave current phase to measure phase who
are, in your words above, the "idiots".

Considering a technical discussion to be fooling the
"experts" speaks volumes, doesn't it? And indeed,
Ian said it best. He said something to the effect that
I try to sucker the experts into an argument when I
am right. That says it all and shows why the "experts"
won't engage me when they know that they are wrong.

Cecil,

You can weave a little tidbit of fact into a big misconception or
diversion if you like, but don't expect others to buy into the
misconception.

The current you measure with a clamp on meter or any other reliable
current meter that does not greatly perturb the circuit is the current
that causes radiation, it is the current that causes heating, and it is
the current we would use to calculate power.

The phase of that current is the phase of the current that causes
radiation, heating, and that we would use to calculate patterns.

One can see from my above graphic that EZNEC indeed does differentiate
between traveling waves and standing waves. So how does EZNEC do that?
EZNEC agrees with your above posting but I don't yet know how it knows.

It's all explained by the EZNEC data that I have posted half a
dozen times before to which you haveyet to responded. In case
you could possibly have missed it, here it is again:

% along current in current in
wire #2 TravWave.EZ StndWave.EZ

0.28% 0.9998 at -0.99 deg 0.9996 at 0 deg
9.72% 0.9983 at -9.39 deg 0.9843 at -0.03 deg
19.7% 0.9969 at -18.23 deg 0.9454 at -0.05 deg
30.3% 0.9957 at -27.59 deg 0.8843 at -0.06 deg
39.7% 0.9949 at -35.96 deg 0.8023 at -0.08 deg
49.7% 0.9945 at -44.84 deg 0.7014 at -0.09 deg
60.3% 0.9945 at -54.20 deg 0.5840 at -0.09 deg
69.7% 0.9949 at -62.58 deg 0.4528 at -0.10 deg
79.7% 0.9956 at -71.43 deg 0.3110 at -0.11 deg
89.7% 0.9965 at -80.27 deg 0.1616 at -0.11 deg
99.7% 0.9976 at -89.14 deg 0.0061 at -0.11 deg

I have graphed these EZNEC results and they are available at:

http://www.qsl.net/w5dxp/travstnd.GIF

The corresponding EZNEC files are available at:

http://www.qsl.net/w5dxp/TravWave.EZ
http://www.qsl.net/w5dxp/StndWave.EZ

Would you please explain why you are avoiding these results
which expose your misconceptions about standing wave current
unless exposing your misconceptions is what you are avoiding?

When are you going to discuss the technical difference
between I(x,t)=Io*cos(kx+wt) and I(x,t)=Io*cos(kx)*cos(wt)?
The only place those two currents are equal is when x=0. At any
other point, they are virtually opposites of each other. The
differences in those two equations is what led you to believe
the currents at each end of a coil are identical based on
measurements. You guys used a signal, the standing wave current
signal, that is incapable of distinguishing a phase shift even
in a wire, much less in a coil.

> The current you measure with a clamp on meter or any other reliable

There's absolutely no argument about that. Both forward waves and
reflected waves radiate so standing waves obviously radiate. Both
forward waves and reflected waves cause I^2*R losses. Stating such
obvious technical facts is a diversion and a waste of words.

> The phase of that current is the phase of the current that causes
> radiation, heating, and that we would use to calculate patterns.

The phase of standing wave current is unchanging. That's why we
get broadside radiation from a 1/2WL standing wave dipole and
end fire radiation from a traveling wave antenna. But again,
stating such obvious technical facts is a diversion and a waste
of words.

When are you going to discuss the actual technical issues?

Before you get too carried away, look back in this thread where Cecil posted a URL to his web site where he had an EZNEC (helical wire) model of a coil at the base of a short whip. It showed significant current drop from the bottom to the top, although no significant phase shift. I replaced the whip part of the antenna with a wire directly to ground from the top of the coil which contained a lumped RC to substitute for the whip's impedance. The drop across the coil remained the same. So in the course of developing your theory, you should explain why this happens, since there are no longer the traveling and standing waves which were on the whip. This model was, and still is, posted on my web site. Then, to illustrate that the current drop from bottom to top is due to shunt C, I removed the ground in the model, converting the model to free space. I connected the bottom of the coil to the bottom of the new wire with a wire instead of via the ground connection. The current drop from bottom to top of the coil disappeared. (There's still a minor difference due to several factors I mentioned in my posting.)

The fact that the current drop is the same for an antenna and for a lumped circuit with the same impedance was also verified by measurements I made and posted over a year ago.

Those model results are consistent with what I, Tom, and others have been saying, and consistent with classical, known, circuit theory. They aren't consistent at all with all this standing wave - traveling wave - antenna replacement business. I've looked very carefully at the models and concluded that EZNEC is operating well within its capabilities, so the results are valid.

So for starters, why don't you explain how your theory fits with the existing model results? Why is the current drop the same with an antenna

and for a lumped circuit? Why does removing ground make the current drop go away? Why is there no significant phase shift in current from bottom to top? Conventional theory can explain this. Can yours?

As for your promise to write the article, I have to point out that you've made this promise before without delivering. So I'm not exactly holding my breath waiting for it. I'm sure it'll make interesting reading, though, and it's a revolutionary enough theory that the IEEE, or at the very least QEX, should be happy to publish it when it's finally complete.

It showed a 10 degree phase shift. I've always said the phase
shift is what it is but it is NOT zero. 10 degrees is definitely
NOT zero even though you measured zero degrees shift. Wonder what
was wrong with your measurements?

> So in

Oh my, Roy, are you saying that zero ohms doesn't cause a reflection?
If so, your misconceptions are worse than I thought. A short to ground
causes exactly the same total reflection as an open-circuit, just with
different phases. I would have expected you to realize that.

> I've looked very carefully at the models

Yes, they are and they shoot down your argument. Please explain
the results posted at: http://www.qsl.net/w5dxp/travstnd.GIF

> So for starters, why don't you explain how your theory fits with the

You first, Roy, since you disagree with EZNEC.

Cecil,

Please humor all of us.

You now seem to agree the current we measure, which is the current that causes radiation, causes heating, and that we can use to determine phase or power levels is what Roy, I, and a dozen others have been saying.

So what exactly is the importance of this current YOU are talking about? Since it does not cause radiation, does not cause heat, and does not determine phase....exactly what does it do?

Cecil,

You may believe it is obvious, but it is not quite clear what you are trying to show in that figure. On the left side, traveling wave, it appears that "magnitude" means Io. On the right side, standing wave, it appears that "magnitude" means Io cos(kx).

The gist of your position seems to be that somehow the traveling wave is more powerful, or at least different, since the area under the current magnitude curve is larger. In reality, however, it is necessary to pick a single time at which to compare the two cases. It is of little value to look at some sort of overall envelope for the traveling wave. The correct magnitude of the traveling wave never has the shape of the overall envelope. Pick a single time, say when wt is equal to zero or equal to pi. Then compare the curves. In fact, if you pick any single time for the left side the resulting curve shape will look a lot like the right side.

Be careful. While we can split a current into traveling wave components, separately calculate the resulting voltages, currents, and field strengths, then add the results to get the total (which is identical to the result of calculating those quantities directly from the total current), we can't do this with power, power density, or heating. If we have two traveling current waves which sum to zero at some point, the total current at that point is zero and the I^2*R loss caused by that current is zero -- regardless of how large the traveling wave currents are. It's not the sum of the heating which would have been caused by each traveling wave independently.

Likewise, we can calculate field strength (E or H) separately from traveling wave components if we so desire (although I can't think of any reason why anyone would want to), then sum the field strengths to get the total. The result will be identical to the field strength calculated directly from the total current as is done by NEC and EZNEC. And you can

calculate a radiated power density from the total field strength. But you can't calculate a radiated power density from each traveling wave component and sum them to get the total power density. Doing so violates the requirements for superposition, and you'll get the wrong answer if you try.

All the diversionary BS trimmed from your posting. Bottom line,
the equation for standing wave current is:

I(x,t) = Io*cos(kx)*cos(wt)

The equation for traveling wave current is:

I(x,t) = Io*cos(ks+wt)

Since you obviously don't comprehend the difference, please
dust off your old math book and take a look.

In case you need a graphics reference for those two equations,
you can find it at: http://www.qsl.net/w5dxp/travstnd.GIF

You will find the two above currents are virtually opposites
of each other.

In particular, standing wave current phase CANNOT be used to
determine the phase shift through a wire or through a coil
because its phase never changes in a 1/4WL monopole.

I can hardly say it better than Gene Fuller who said:
Regarding the cos(kz)*cos(wt) term in a standing wave:

No, both plots are for I(x,t). The magnitude of the traveling wave
current is constant while the phase changes with 'x'. The phase of
the standing wave current is constant while the magnitude changes
with 'x'. They are virtually opposites of each other.

> It is of little value

Both currents are phasor RMS values along with their phases.

I am reporting *exactly* what EZNEC reports. If you don't like
that, talk W7EL into reporting something different.

perhaps just making a wood board or somthing to fill a few inches and
cut to allow the window to close on it, w/foam too and drill a hole in
the wood to pass the wire and have it centered enought away on all
sides from metal then it dosn't disturbe or damage the building/window
etc

Cecil,

Perhaps I was not clear. I understand the plots, and I have no question
that they show what EZNEC provides.

My question is why you feel there is anything of significance or
anything for the "gurus" to ponder.

As I explained, the curves are mostly a comparison of apples to oranges.
One (standing wave) shows the peak current at when the cos(wt) factor is
at a maximum. The other (traveling wave) shows the envelope of all the
current shapes over time. They are really two different entities, and
they have virtually no application to the topic featured in the past
17,000 messages.

What you call the "magnitude" of the traveling wave never actually
represents the current over the length of wire at any point in time.

73,
Gene

> trying to show in that figure.

Gene, I previously responded in words that I thought you would understand, based on your previous understanding. It occurred to me during my walk that not every reader is an engineer, not every engineer is a EE, and not every EE also has a math degree.

Here it is in easier to understand terms. Given the 1/4WL conductor and the web page at:

http://www.qsl.net/w5dxp/travstnd.GIF

The way to measure phase shift through a wire carrying the traveling wave current is to put a current probe at location A and location B, and measure the phase shift between those two equal magnitude sine waves. If a coil exists in the circuit, that would also be the way to get a rough measure of the phase shift across the coil.

Example: The phase shift from 30% to 60% in the traveling wave antenna is taken from the tabular data as 54.2-27.6 = 26.6 degrees.

The phase information is in the *phase* in a traveling wave.

For the standing wave current, the situation is completely different. The phase measured between any two current probes will always be zero. The phase of a standing wave current is useless for measuring phase shift. The way to extract the phase information is to measure the *amplitude* at two points and then calculate the phase shift by taking the arc-cos of the normalized amplitude.

Example: The phase shift from 30% to 60% in the standing wave antenna is arc-cos(0.8843) - arc-cos(0.5840) = 26.5 degrees.

The phase information is in the *amplitude* in a standing wave.

Thus in both antennas, the phase shift in 30 percent of the wire is about 27 degrees. (90*.3 = 27) If we had a coil installed in that 30 degrees of the antenna instead of a wire, the same concepts would apply.

Maybe one of my other postings answers the question for you.
I'm not prevaricating or deviating. I'm answering the questions
to the best of my ability. Gene's posting is one of the best
answers to Tom's questions that I have seen. Gene says there is
ZERO information in standing wave phase. I agree with Gene.

> Except for this particular subject I have great admiration for you

The object of the exercise is to prove that standing wave current
phase cannot be used to measure the phase through a wire or coil
or anything else. The phase of a standing wave is already known
and is unchanging. The only phase information in a standing wave
current is contained in the amplitude.

Sorry, I forgot to mention that they also don't appear to understand
math, or the fact that "complex numbers" are quite simple if you went to
engineering school and own an HP15 calculator. Mine still works fine.

If you had trouble with the previous statement, Cecil and Yuri, I meant
that your "phasor" math is trivial. At best 2nd year engineering. And
yes, we do understand it. A lot more than you do apparently.

Hopefully, I answered that question in my other posting. If one wants to measure phase shift using a traveling wave current, one measures the phase shift between two points.

If one wants to measure the phase shift using a standing wave current, one measures the amplitudes at two points and subtracts the arc-cosines of the normalized amplitude values.

You said essentially the same thing in your earlier posting - that there is no phase information in the standing wave current phase and all the phase information is in the amplitude values.

Well then, please prove W8JI's assertion that "current is current",
i.e. that cos(kx+wt) = cos(kx)*cos(wt) at every point up and down
the wire. That should be "trivial" for you.

If you cannot prove that, please explain to us how and why
standing wave current is different from traveling wave current.
(That's what I have been doing.)

During your explanation of the difference, you will realize why
W7EL's standing wave phase measurements are meaningless - that
there is no phase information in standing wave current phase.
As Gene said, all the phase information is in the standing wave
current *amplitude*, not in the phase.

560. Gamma. Before somebody tells me.

Newsgroup: rec.radio.amateur.antenna
Date: 2006-04-08 01:22:19 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <EtCdndvtWbAWjarZRVnyrg@bt.com>
Source record: 61402

Before somebody tells me there's something wrong with programs
LINE_ZIN and INPUT_Z I'd better put in a few words of explanation.

First of all there's nothing wrong with the programs. Both are
correct.

They both calculate the reflection coefficient Gamma for a given line
and given load impedance at a given frequency. One does it for coaxial
lines and the other for balanced-twin and open-wire lines.

But, believe it or not, under certain load conditions the reflection
coefficient Gamma can exceed unity. Indeed, at a sufficiently low
frequency, Gamma can approach 1+Sqrt(2) = 2.414

With program LINE_ZIN enter the following -

Freq = 0.2 MHz
Conductor diameter = 0.2 mm
Conductor spacing = 10 mm
Line length = 119.25 metres
Velocity factor = 1.00
Load resistance = 0.00 ohms
Load reactance = + 552.6 ohms

From which we get -

Zo = 552.6 ohms
Gamma = 1.084
Angle of Gamma = -90.0 degrees
SWR at load end = 24.8
SWR at input end = Infinity

With program INPUT_Z enter the following -

Frequ = 0.2 MHz
Zo = 50 ohms
Line length = 100 metres
Inner conductor diameter = 0.73 mm (RG-58)
Velocity factor = 0.66
Load resistance = 0.00 ohms
Load reactance = +50.00 ohms

From which we get -

Gamma = 1.109
Angle of Gamma = -90.0 degrees
SWR at load end = 19.3

The reason for the abnormally high values of Gamma, and the SWR at the input end being higher than the SWR at the load end, is that the line impedance Zo is not purely resistive. It has a negative angle. Zo = Ro - jXo.

There is a resonance between -jXo and + jXload which causes the reflected wave to be greater than the incident wave. Hence Gamma exceeds unity. The effect is not present when jXload is negative.

Gamma has a maximum value when +Xload = Zo as can be found by varying Xload on either side of Zo.

At some distance back from the load the extraordinary high value of SWR occurs (as demonstrated with program LINE_ZIN) due to that point taking the place of the end of the line when Zo is purely resistive.

The true value of Zo = Ro+jXo can be found by making the line long enough such that attenuation exceeds about 35 or 40 dB. Line input impedance is then becomes equal to Zo.

It is the fact that Zo is never purely resistive which causes errors when using the Smith Chart. Errors which the user can be entirely unaware of. Coax lines are more prone to error than higher impedance balanced-twin lines.

The reason why both programs stop at 200 KHz has nothing to do with the foregoing. It is due to skin effect not being fully operative at lower frequencies which complicates calculations.
There are other programs which go down to audio and power frequencies.

Reg, G4FGQ

That agrees with Chipman who says it only occurs in lossy lines.

Oh, I know all that.

I'm not posting in an attempt to educate Cecil and Yuri or to change their minds -- it became evident years ago that's a waste of time. The only reason I bother is in the hopes that it'll play some part in preventing some of the lurkers from getting sucked in by the flurry of informed-sounding but demonstrably wrong arguments which continue to come from those folks. It's hard to say if it's having any effect, but I think it's important to present a point of view supported by established theory, modeling, and measurement results which are all in agreement rather than letting the pseudo-science stand alone as apparent fact.

Roy, it is demonstrably wrong to try to use standing wave current
phase to measure the delay through a coil. Anyone, including you,
who says it is a valid procedure is either ignorant or trying to
hoodwink the lurkers.

Guess you misunderstood. A coil can replace 30 degrees of
an antenna but it won't use the same amount of wire as
30 degrees of wire. What I said is that an inductor is
more efficient than linear loading.

I was taught that under these circumstances DC and RF work differently.
Yes your DC net current is zero. Your new RF current is one amp in each
direction.

Agree.

But, whether you're doing your testing or operating afterward, there's
usually some value in knowing the VSWR in the line. It may only serve to
clue you to a problem -- and that's info worth having. I'm depending on the
slightly risky assumption that most tuners you test will be able to match to
a less-than-ideal antenna system with high VSWR in the feedline -- one
that's not putting much power into the air.

I had a USN antenna experience with an improperly-modified shipboard HF XMIT
antenna. The Radiomen said it was hard to
tune to it, the reflected power was always high and they never seemed able
to "get out on it" (meaning poor reception reports from the distant end).

When we put the antenna right, all their problems went away.

580. Feeding 2 VHF Yagis from one coax?

Newsgroup: rec.radio.amateur.antenna
Date: 2006-04-08 11:02:06 UTC
From: Scott <acepilot@bloomer.net>
Message-ID: <QdSdnTOhuJSyBarZRVn-vw@bright.net>
Source record: 61422

I have a temporary tower set up with a 6M yagi on it. I'd like to add a 2M yagi. Is it possible to feed the two antennas with one feedline similar to feeding multiple HF antennas with one feedline?

Coax from Shack RG-8 RG-8
==========T==========2M Yagi
I
I RG-8
I
6M Yagi

So basically, I would add a T connector at the 6M Yagi and run another piece of RG-8 from the T to the 2M Yagi (the T connector would have a male PL-259 on one port connected directly to the 6M Yagi, the other 2 ports are female UHF and one would be connected to coax from shack and the other would have the jumper to the 2M antenna). Now the $64K question...should the run of RG-8 from the T to the 2M be a certain length, such as 1/4 or 1/2 Wavelength at one of the bands and if so which band? i.e., 1/2 wavelength at 6M or 1/4 wavelength at 2M, etc. Both antennas use a gamma match as the feed, so the short section of coax seems like it might be perceived as a open-ended stub attached to the 6M antenna??? This is for high speed meteor scatter, so I'm not overly concerned if the antenna patterns get a bit screwed up...

thats the basic problem in this whole discussion. you are all talking about the same thing, just using different notation and incomplete statements so that none of you understands exactly what the others are trying to talk about... when really you are all saying the same thing. its kind of like after i graduated from college with an ee degree and my sister graduated from an air force basic electronics course, she tried to ask me something about currents in a transistor and i saw it all backwards... well of course she was talking electron flow and i was talking hole flow. we both got the same result but the notation was all different.

so, now i will raise my voice...

STOP THIS PETTY BICKERING AND GET OUT THERE AND USE AN ANTENNA INSTEAD OF ARGUING ABOUT WHY THEY DON"T WORK THEY WAY YOU THINK THEY SHOULD!

If one doesn't understand sinusoidal waves, one doesn't have
a ghost of a chance of understanding a pulse train. Trying
to introduce a pulse train before understanding sinusoidal
values is just muddying the waters.

In a closed system, such as a source, transmission line, and
receiver, ghosting represents reflected waves.

For an EM wave in a lossy environment, the attenuation factor
applies equally to the E-field and H-field, i.e. equally to
voltage and current. Both "drop" at the same rate.

The transmission line voltage equation contains that attenuation
factor and the current equation is simply the voltage equation
divided by the characteristic impedance.

In a lossy transmission line, the H-field and E-field "drop"
at the same rate since their ratio is fixed by the
characteristic impedance.

One more proof that EM waves are NOT lumped circuit voltages
and currents.

Yes, that is true, but EZNEC doesn't report the two separate currents. EZNEC reports the phasor sum of those two currents in magnitude and phase. So the question still remains: In which direction is the total current reported by EZNEC flowing? What does the unchanging phase really mean?

EZNEC says that, referenced to the source phase, the phase of the phasor sum of the forward and reflected currents is UNCHANGING. It makes no sense to pick a direction of flow for the sum of two equal currents flowing in opposite directions.

Standing wave current doesn't flow in the commonly accepted meaning of "flow". Standing wave current just stands there.

I received the following email from a physics professor:

"As for the standing waves, they really aren't independent creatures. They're an artifact - a construct which happens to look like the superposition of fields which surround the antenna. But the fields which superpose look like the traveling waves. The traveling waves really tell the story."

Dave wrote:
> ... when really you are all saying the same thing.

Unfortunately, we are not all saying the same thing.
W7EL and W8JI are saying that using standing wave
current phase to make a phase shift measurement is
a valid approach. They keep reporting their results of
using such an approach as if it were a valid thing to
do. When those useless phase measurements are discarded,
the technical picture becomes a lot clearer.

I, and others, are saying that using a signal with
unchanging phase will not and cannot tell one anything
about any phase shift. There is no phase information
contained in the standing wave phase. All of the phase
information is contained in the standing wave magnitude.

I'm building a web page about this subject. The initial
graphic is at: http://www.qsl.net/w5dxp/travstnd.GIF

Note that for a standing wave current, the only thing
changing with length is magnitude. The flat phase line
of the standing wave current is completely useless for
making phase measurements.

Hi Scott

No doubt others will give you much better info than I.

The gamma macth feed is irrelevent. If you have a resistive 50 ohm load for each antenna at its operating frequency it makes the maths of using tuned coax lengths a little easier. I would have to sit down and think about it a bit deeper but on the surface it looks like;

Use a 1/4, 3/4, 5/4 etc wavelength of coax on 2M to attach the 6M antenna to the T piece. The logic is that the lowish impedance of the 6M antenna on 2M will be transposed to a high impedance at the T piece, the net result being little effect to feeding the 2M antenna.

Do the reverse when feeding the 2M antenna.

Problem - There is a relatively close harmonic relationship between 6M and 2M. ie a 1/4 wavelength on 6M is close to a 3/4 wavelength on 2M. If you think about it you will note that any 6M length will also be a 2M length! You cant actually get away from the problem! This feeding technique is only really usable when there isnt a 3:1, 5:1 etc frequency relationship.

You are welcome to a spare coaxial relay I have! I dont however have spare N connectors. If you want it pls email me direct.

Cheers Bob W5/VK2YQA East Texas

That's not true at all Dave. Most of us know that current is current. It really only flows one direction at any instant of time. We can indeed consider systems as having current that flows two directions at one instant of time, but the results of that better agree with the actual real current that flows only in one direction at any instant of time or they are wrong.

Also, behavior of basic components cannot change. A two terminal device like a loading coil cannot have differences in the current flowing through it at each terminal without a third path. (I assume we all know current is not an across vector and it does not "drop", the person who started this thread just used poor wording.)

I think the basic problem is Cecil wants to used some definition of current that does not allow models to be freely exchanged and does not produce results that match real world systems. It always has to match. We can't have different results unless someone has an error.

The only reason I'm skimming the posts here and making the occasional comment is I hate to see people trying to understand how this stuff works be confused. The real fuss is a couple people seem to think standing waves or "missing antenna length" are the root cause of current being different in the two terminal component called a loading coil.

It really isn't an argument or debate as much as trying to help lurkers understand how the system really works, and not let them fall into the trap that the loading coil behavior is any different than any other coil, the only possible reason for differences in current at each terminal is stray capacitance allowing displacement currents to the outside world, and that any phase differences in current at each coil terminal are also tied to capacitance from the coil to the world around the coil.

It's not correct to assume people are talking about the same result different ways, because both Cecil and Yuri have huge flaws in their conclusions. They both seem to want the inductor to behave in some very unique way just because it is an antenna, and the reults they seem to claim do not match actual measurements. Cecil dismisses real measurements with frantic arm waving about reflected and forward current and no one being able to measure current and phase because of standing waves, and while I think Yuri would accept measurements he won't accept them when made by others and won't make them himself.

This has gone on for perhaps three years now. It is really up to Cecil and Yuri to let it go, since they are the ones who seem to disagree with measurements and accepted theory.

ARGH! maybe it really is more basic than different notations and
terminology. when working with antennas and 'component's that are a
significant fraction of a wavelength in size you must take into account the
'third path'... the 'third path' consists of the distributed capacitance and
resistance that CAN be modeled with lumped components if you want to go
through all the approximations and extra calculations that are required. if
you are ignoring that 'path' when talking about relatively large loading
coils then you will be wrong, how wrong depends on how large of course.

i haven't been following all the different threads and junk in here, but if
you are trying to analyze a significant sized loading coil without taking
into account all the paths then you are going to likely be less accurate
than cecil using a more complete distributed model. OBVIOUSLY if you are
using a strict lumped model the current can't be different from one end to
the other. And just as obviously if you make a really large loading coil,
like a full '1/2 wave' slinky dipole, the current at the feedpoint end will

be MUCH different than at the open end. You can both get the same results, but to do it with lumped elements requires the same calculations that are done by finite element simulations that try to do enough small lumped elements as possible to approximate the distributed equations that would give nice smooth results. Unfortunately cecil does not do a good job in relating the distributed model, and his constant references to 'optics' and the use of terms related to that field do nothing but confuse many of the people in here to think that he is in a different world. admit it cecil, while you may be correct, using a different set of terminology than most of the people in here has done nothing but add to the confusion factor in many of this long drawn out threads.

I still think that if each of you explained the WHOLE problem in your own terminology, INCLUDING all the assumptions that are required for the models you are using, that you would find that each of you is correct. but because you are starting from different sets of assumptions you will never find a common ground.

enough of this, back to assembling my new linear loaded 40m beam... why don't you go analyze that loading system for a while.

If you ignore it now, at least everyone will know you couldn't
possibly have missed it.

You are in a room with a 50 ohm transmission line routed
through a hole in one side of the room, across the room,
and through a hole in the other side of the room. You don't
know which is the source end of the line. A directional
wattmeter reads 200 watts forward power and 200 watts
reflected power but you don't know which direction is
forward. Here's a diagram:

200W--> 2 amps-->
hole-------------------50 ohm coax-------------------hole
<--200W <--2 amps

Which direction is the standing wave current flowing?

If you knew forward current was moving left to right which
direction would the standing wave current be flowing?

> That's not true at all Dave. Most of us know that current is current.

Too bad EZNEC disagrees with you as seen in the graphic at:

http://www.qsl.net/w5dxp/travstnd.GIF

The traveling wave current is virtually the opposite of the
standing wave current as can be seen by their different
equations. There is no phase information in the standing
wave current phase. Yet that is exactly the phase W7EL
used to try to measure the delay/phase shift through a
coil.

DC current is different from AC current. That's why the
DC or AC designations are necessary. RF forward current
is different from RF standing wave current. That's why
the different designations are necessary.

> It really only flows one direction at any instant of time.

Or not at all at a standing wave current node.
Too bad we are talking RMS values here which is what EZNEC
reports. I'll ask the question of you: If one amp of RF
current is flowing in one direction and one amp of RF

current is flowing in the opposite direction, which direction
does the phasor sum of those two currents flow?

> We can
> indeed consider systems as having current that flows two directions at
> one instant of time, but the results of that better agree with the
> actual real current that flows only in one direction at any instant of
> time or they are wrong.

The phase of standing wave current is unchanging. It doesn't "flow"
in the commonly accepted sense of the word. As Hecht says in "Optics":

"This is the equation for a STANDING or STATIONARY WAVE, as opposed
to a traveling wave. Its profile does not move through space; it is
clearly not of the form Func(x +/- vt)."

[Standing wave phase] "doesn't rotate at all, and the resultant
wave it represents doesn't progress through space - its a standing
wave."

If standing wave light doesn't move through space, then standing
wave RF also doesn't move through a wire.

> (I assume we all
> know current ... does not "drop", ...)

EM current does indeed drop exactly like EM voltage drops both
according to the attenuation factor. Just one more proof that
EM waves are not lumped circuit currents. The only difference
in the equation for transmission line voltage and current is
the voltage gets divided by the characteristic impedance which
is usually a resistive constant.

> I think the basic problem is Cecil wants to used some definition of
> current that does not allow models to be freely exchanged and does not
> produce results that match real world systems. It always has to match.
> We can't have different results unless someone has an error.

Exactly correct and the reason for the different results is your
error. In any conflict between the distributed network model and
the lumped circuit model, the distributed network model wins
every time since it is a superset of the lumped circuit model.

> This has gone on for perhaps three years now. It is really up to Cecil
> and Yuri to let it go, since they are the ones who seem to disagree
> with measurements and accepted theory.

On the contrary, it is up to you and others to correct your
misconceptions about standing wave current. Your "accepted
theory" has holes in it that I could drive my GMC pickup
through.

Cecil,

I am feeling dizzy. I am quite comfortable with my understanding of the entire problem, but I am seriously confused about your position. Nobody has ever talked about efficiency or the length of wire needed. The issue has always been replacing "degrees of antenna". I have captured a few excerpts from April 7.

73,
Gene
W4SZ

Excerpt follow:

9:03 am -- From Cecil

K7ITM wrote:

> Another 'speriment occured to me, for those who think the coil current
> MUST be different at the two ends by the amount corresponding to the
> antenna section it replaces:

To the best of my knowledge, nobody believes that. The coil is much more efficient at the loading function than is the straight wire from which it is made. That's why inductive loading is more efficient than fractal antennas or other types of linear loading.
--
73, Cecil http://www.qsl.net/w5dxp

9:24 am -- From Yuri

[excerpt]

Now you move that coil say half way up the must, to higher impedance point at the antenna, and that coil now, in order to maintain the "match" has to have higher impedance, more turns and will exhibit MORE

current drop across it, while replacing THE SAME NUMBER OF "missing" DEGREES AT THE RADIATOR.
Assuming that our goal is to stay with the same physical length of the whip (which we do) and maintaining 90 degrees of resonant radiator. So the radiator stays 50 degrees ()+50, 10+40, 20+30, 30+20, 40 + 10) long and coil replaces the same "missing" 40 degrees.

[emphasis was in the original message]

9:44 am -- From Cecil

Roy Lewallen wrote:

> Of course loading coils can be expressed in electrical degrees. But extrapolating this to mean that a loading coil has the same properties as an antenna with the same number of "degrees" has no justification.

I haven't heard anybody make that assertion in years. Coils occupy whatever number of degrees that they occupy.

8:49 pm -- From Cecil

[excerpt]

Example: The phase shift from 30% to 60% in the traveling wave antenna is taken from the tabular data as 54.2-27.6 = 26.6 degrees.

The phase information is in the *phase* in a traveling wave.

For the standing wave current, the situation is completely different. The phase measured between any two current probes will always be zero. The phase of a standing wave current is useless for measuring phase shift. The way to extract the phase information is to measure the *amplitude* at two points and then calculate the phase shift by taking the arc-cos of the normalized amplitude.

Example: The phase shift from 30% to 60% in the standing wave antenna is arc-cos(0.8843) - arc-cos(0.5840) = 26.5 degrees.

The phase information is in the *amplitude* in a standing wave.

Thus in both antennas, the phase shift in 30 percent of the wire is about 27 degrees. (90*.3 = 27) If we had a coil installed in that 30 degrees of the antenna instead of a wire, the same concepts would apply.

I have a limited technical library. I wish my RF references spelled out
everything as well as "Optics", by Hecht, but mine don't. Light and RF
are the same kind of EM waves, just at different frequencies. Hecht's
material is certainly relevant to RF waves. And I make every effort to
translate the technical jargon from one field to the other as best I
know how.

Hecht presents the best treatment of superposition, interference,
and standing waves that I have ever seen. I wish I had an RF
reference book as well written as "Optics".

What you quoted from me is my reporting of what EZNEC says about
standing wave current Vs traveling wave current at:

http://www.qsl.net/w5dxp/travstnd.GIG

The 'x' axis for both conditions is just a piece of 1/4WL wire.
One can calculate the phase shift in any section of wire in two
ways:

1. For traveling waves, the phase shift is given by the graph
of the phase (red line). The magnitude (blue line) contains
no phase information.

2. For standing waves, the phase shift is given by taking the
arc-cosine of the magnitude (blue line). The phase (red line)
contains no phase information.

Before we talk about replacing a piece of wire with a coil,
do you understand the above graphic and concepts? You seemed
to understand when you posted:

Regarding the cos(kz)*cos(wt) term in a standing wave:

Gene Fuller, W4SZ wrote:

Lets also say that the wavelength of the waves passing through this transmission line are as long as the room is wide (one wavelength fits inside the room.

Then we can say that at any moment when the instantaneous magnitude of he current is not at zero (and it will pass through zero all along the line simultaneously, right?), the current will going in one direction in half of that length *with varying magnitude) and the other way in the other half (also with varying magnitude). I am not saying that the direction reversal will necessarily be at the center, but that is one possibility.

For example, if we took a snapshot of the current, all along the line at the moment it peaked it might look like this:(length of arrow represents current magnitude, and head shows direction)(view in fixed width font)

```
....---> ---> --> -> <- <-- <--- <--- <-- <- -> -->......
hole-------------------50 ohm coax-------------------hole
```

This is a snapshot of the current all along the line at an instant.

A quarter cycle later, the current would be zero, everywhere.

A half cycle later (than the first snapshot) it would look like this:

```
....<--- <--- <-- <- -> --> ---> ---> --> -> <- <--......
hole-------------------50 ohm coax-------------------hole
```

This is the pattern the standing wave function describes. The current at every point has one of two phases, which are 180 degrees from each

other.

Is this how you see it?

Agreed, with one exception.

There is a phase reversal each time you pass through a node, so you
can tell by phase measurement, if you are on the far end of an odd
numbered node or an even numbered node, once you decide which of the
two possibilities of the phase is at the far end of node zero (or some
other reference point). But between any pair of nodes, yes, you have
to use the phase information obtained from the ARC-COS(magnitude), or
the distance from that point to a node (as a fraction of a wavelength
in the line), to infer where you are within that half wavelength.

Of course, you can find the node either as a point with zero
magnitude, or the point between phase reversals.

I have to agree, Dave.
It kind of makes sense that if a signal is strong enough fight its way up the
stainless steel, and then out through the fibreglass that it is
most certainly strong enough to hit any receiver.

You are correct if two sides of a node exist in the system.
But since the context was my above 1/4WL wire, there is no
"passing through a node". I was limiting my statements
in context to a 1/4WL long conductor.

> Yes, now which direction is that current flowing?

You deleted the arrows which I drew that showed one possible case. Do
you have some argument with what you deleted?
(I'll replace it, so you don't have to go back to look at it)
(begin paste)

For example, if we took a snapshot of the current, all along the line
at the moment it peaked it might look like this:(length of arrow
represents current magnitude, and head shows direction)(view in fixed
width font)

```
....---> ---> --> -> <- <-- <--- <--- <-- <- -> -->......
hole--------------------50 ohm coax--------------------hole
```

This is a snapshot of the current all along the line at an instant.

A quarter cycle later, the current would be zero, everywhere.

A half cycle later (than the first snapshot) it would look like this:

```
....<--- <--- <-- <- -> --> ---> ---> --> -> <- <--......
hole--------------------50 ohm coax--------------------hole
```
(end paste)

See all those arrows of various length representing current direction
and magnitude? Why do you ask me about something after erasing my answer?

> If the source were known to be to the left, would that change
> your answer?

For a pure standing wave, there is effectively a source at each end,
so this question is meaningless.

So, add some transmission line to the system so a node's location is
measurable inside the system. By the way, in case you didn't notice,
I am agreeing with you, and elaborating on what you are saying.

This sounds like a common theme. A shortwave station, intended audience being the US, sidestepping FCC regulations by aiming a barely directional antenna at the northern tip of Mexico. There are a number of stations doing just this. The majority of their programming is far right religious with the occasional fringe "militia", conspiracy freak, and doomsday predictor thrown in. Don't plan on getting rich. In fact, you may well have trouble staying on the air. The sort of people that you will be dealing with are often less than trustworthy. Watch your back.

Hello, I have Balanis' Antenna Theory 3rd Edition. I read on page 31 at the very last sentence that "Side lobe levels of -20 dB or smaller are usually not desirable in most applications."

Why? On the same paragraph it states that "minor lobes represent radiation in undesired directions, and they should be minimized." If a side lobe is a minor lobe, then why is it undesirable to have side lobe levels less than -20 dB? Thanks!

Hi Ron,

If it were one side lobe, that would be great. If it is several dozen
minor side lobes, then that is entirely another matter. The antenna
design is devoting too much power in this aggregate.

Exactly! Now try to tell that to W8JI and W7EL who attempt to
assign a direction of flow to standing wave current and use
its phase to determine the phase shift through a wire or coil.

That's easy, Richard. The current pickup in the SWR meter
will read zero at a standing wave current node. It's a
good thing that an SWR meter is not 100% dependent upon
a current flow reading, eh?

What are you calling "standing wave current flow"? Describe or define it.

Are you actually saying charges flow two directions at the same time and place in any given snapshot of time?

The current we would measure at any place with a current indicator and the phase of that current IS the actual current flow. Any solution breaking it down into forward and reflected current has to produce the same answer as the measurement, and that current (as you agreed earlier) is the current responsible for radiation, heating, and phase of the radiated field.

It is impossible to have different currents at each end of the inductor without having displacement currents, or what Reg calls "radial current flow".

Why are you complicating your life with something that seems to be giving you the wrong answer? More important, why do you want the rest of the world to share in having the wrong answer?

The same standing wave current that you and W7EL used to make
your current measurements on standing wave antennas.

> Are you actually saying charges flow two directions at the same time
> and place in any given snapshot of time?

Water waves flow two directions at the same time using the same
water molecules. EM waves flow two directions at the same time
using the same carriers. Waves in a rope travel two directions
at the same time using the same molecules. It is a common physical
occurrence. Hint: The carriers of the waves are NOT the same thing
as the waves.

> The current we would measure at any place with a current indicator and
> the phase of that current IS the actual current flow.

What direction is that current flowing when its phase is not
changing relative to the source phase? This is a key question.

> It is impossible to have different currents at each end of the inductor
> without having displacement currents, or what Reg calls "radial current
> flow".

We have different currents at each end of a wire quite often
without having displacement currents. Does having zero amps
and one point and one amp 1/4WL away mean there's displacement
current in a transmission line? When you figure out the answer
to that one, you will understand why the coil can have negligible
displacement current and still have zero amps at one end and
one amp at the other end, just like the wire or transmission line.

Source--------------a-/////////-b------------------------------

Measured current at 'a' is zero amps. Measured current at 'b' is
one amp. Where is the current at 'b' coming from? Certainly NOT

from displacement currents.

> Why are you complicating your life with something that seems to be
> giving you the wrong answer?

Actually, I am complicating your life with something that gives
the correct answer. If you will fix your misconceptions about
standing wave current, everything else should be just fine.

And any one of those molecules that participate in the process move in
a circular motion, if the process is a pure traveling wave, or up and
down if the process is a pure standing wave.

> EM waves flow two directions at the same time

The current in the wire must be in one of two directions, since that is
the only path the wire can provide. However, there are also radial
displacements driven by the rate of change of voltage at each point
along the wire. The displacement currents are what allow the current
in the wire to be different at different points. If there were no
dosplacement curents, the speed of light would be infinite and there
would be no waves.

> > It is impossible to have different currents at each end of the inductor
> > without having displacement currents, or what Reg calls "radial current

Impossible. Any conductor with changing voltage has displacement
current to ite surroundings.

> Does having zero amps
> and one point and one amp 1/4WL away mean there's displacement
> current in a transmission line?

If there is non zero amps nearby, that is exactly what it means.

> When you figure out the answer
> to that one, you will understand why the coil can have negligible
> displacement current and still have zero amps at one end and

You cannot have a transmission line without displacement currents.

> Source--------------a-/////////-b------------------------------
>
> Measured current at 'a' is zero amps. Measured current at 'b' is

> from displacement currents.

I disagree. every conductive surface with varying voltage on it has
displacement curent, whether that surface is part of a transmission
line, a coil, or an antenna.

> > Why are you complicating your life with something that seems to be

You can have no waves in transmission lines, coils or antennas without
displacement currents. They are half of what supports the waves and
determines their speed.

Who said anything about the meter movement? We are talking
about the RF current magnitude which indeed can be zero.

When the RF standing wave current magnitude is zero, it just
means that all the energy is stored in the standing wave
voltage which is half of the SWR measurement.

In which direction is that current flowing when its phase
is unchanging with respect to the source?

> Any conductor with changing voltage has displacement
> current to ite surroundings.

Which are quite often negligible compared to the effect
of the phasor addition of forward and reflected currents.
All I am saying is that the displacement current to ground
is often a secondary effect which can be ignored when only
primary effects are being considered.

My experience is that the velocity factor of foam dielectric cable like RG8X varies considerably from batch to batch and manufacturer to manufacturer. Apparently they have poor control over the foam density in the manufacturing process. For any application where it really matters, you really have to measure it for the particular piece of cable you'll be using.

Yes, what happens if the current sample is zero is that the
forward power indication and reflected power indication are
the same and indeed Vv - Vi = Vv + Vi = Vv. The indicated
forward power and reflected power are equal just as they
should be.

But the trivial point that Richard C. was making is that the
meter movement requires current - true but completely
irrelevant.

> as the waves.

Current is by definition is the flow of charge.

A current of one coulomb per second is one ampere.

By definition and by physics, we cannot have charges flowing two directions at once at one point. Even if we had some strange mechanism in the conductor allowing this, radiation and the phase of EM fields would be determined by the net charge movement.

This is precisely the current we would measure with a current meter sampling the magnetic field, it is the current we would measure sampling radiation, and it is the current that would determine phase of the radiation or induction field.

So please expain to use, even if we allow a conductor to have TWO voltage gradients of opposite polarity over the same linear area of conductor, why Cecil's Current is important.

Also, tell us how we can measure and prove in a repeatable test, the two-way charge movement exists.

> > The current we would measure at any place with a current indicator and
> > the phase of that current IS the actual current flow.
>
> What direction is that current flowing when its phase is not
> changing relative to the source phase? This is a key question.

Either you are creating diversionary conundrums, or you should be able to explain how we can have charges moving past a point in a single conductor that are moving both directions at one instant of time. Tell us how that happens. Tell us why we suddenly cannot use drift velocity to calculate current, or current to calculate drift velocity.

The almost universal measurement method of current is magnetic. Suddenly Cecil's Theory of Current renders universal measurement

methods obsolete!

NEC uses current and voltage, not wave theory. You attempt to use an engine that uses what you say we can use to prove we are wrong in using current when there are standing waves!

Don't you think you should have understood the NEC engine used in the program before using it to prove we cannot use current without reflections? Eznec uses the very same thing we can measure with a clamp on meter, so it appears you are the one who is doing something wrong.

> > It is impossible to have different currents at each end of the inductor

> > flow".
>
> We have different currents at each end of a wire quite often
> without having displacement currents. Does having zero amps
> and one point and one amp 1/4WL away mean there's displacement
> current in a transmission line?

Yes, absolutely. If you don't understand that, you'd better review basic transmission lines and quit wasting everyone else's time giving assignments.

>When you figure out the answer
> to that one, you will understand why the coil can have negligible
> displacement current and still have zero amps at one end and
> one amp at the other end, just like the wire or transmission line.

Nonsense Cecil. I'd wager almost everyone here understands transmission lines better than that!

It appears you have wandered off into the land of reflections without also understanding basic circuits. The transmission line can be represented as a network of series inductors and shunt capacitors, just as an antenna (even a single conductor) in space can. The only reason current changes is displacement currents (the electric field) allow current to decrease by providing the third path.

If we stopped that third path, the current would not change.

We can analyze any stub with EXACTLY the same results wave theory produces. Other than imperfect precision in both methods, the results are the same.

The minute any of us start thinking there is only one model, either circuit or wave theory, that works and we cannot fit the other method with the same results, it shows something is wrong. Your model, if you rule out displacement currents, cannot work. Your model, if it requires net current flow that does not register as a magnetic induction field or as a thermal effect, and if the radiation phase and level is not tied to the same ampere-feet we measure with conventional instrumentation, is a fantasy.

Go back to what makes charges move, and explian how thay can move two directions at the same time in a very small crossection of conductor in terms of the wavelength.

Answer the question Cecil, how can we have charge movement over a small length of conductor (in terms of the wavelength) in two directions at the same time, or a drift velocity in two directions at once?

> is unchanging with respect to the source?

At any point along the wire, and at any particular instant, whether as a result of a standing or traveling wave, the current flows in the direction of the wire, one way or the other. Such current does not have a phase. It has a direction. The sinusoidal cycle of variation through time is what has a phase with respect to some reference. The cycle of current in a standing wave, at any point has one of only two phases.

There is also a current at any point that passes between the surface of the wire and the surroundings (capacitive current), but you don't generally measure or describe that current when dealing with antenna elements, transmission lines or coils. You generally quantify only the current in the direction of the wire. But it is the displacement current radial to the wire that is responsible for all variation of current (magnitude and phase) along a conductor.

>> Any conductor with changing voltage has displacement
>> current to ite surroundings.
>
> Which are quite often negligible compared to the effect
> of the phasor addition of forward and reflected currents.

Those wave currents could not travel at nearly the speed of light without the displacement currents. They are what set the wave velocity (in conjunction with the inductance per length). They can never be forgotten when dealing with waves. They allow waves to happen.

> All I am saying is that the displacement current to ground
> is often a secondary effect which can be ignored when only
> primary effects are being considered.

Then you are silly. You cannot describe the reason for wave velocity of a conductor, transmission line or EM wave without displacement current. It would like trying to describe water surface waves without referring to the density of water.

For instance, when there is a standing wave current node, and current is toward that node (charge is piling up), from both sides, where do you think it is going?

There is only one place.

Displacement current into the space around the node.

And at the node where current is instantaneously heading from the node, in both directions (that is what 180 degrees across the node means), simultaneously, there is only one place it can come from. Displacement current from the space around that node.

If you superimpose the graph of standing wave voltage along the line with the graph of standing wave current, you will see that the voltage wave has its peaks at the current nodes, and it is this large voltage swing that is driving the peak displacement current at those points.

So please stop saying that displacement current is negligible in some cases of traveling or standing waves. It is a silly thing to say.

From: John Ferrell <johnferrell@sprintmail.com>
Message-ID: <jlng32pjgnprbk16mg6v6lgsife44fss1b@4ax.com>
Source record: 61280

I am experimenting with insulated radials on a vertical antenna.
They are insulated wires on top of the ground.
I have modeled it with EZNEC but I cannot model the center junction
connected to ground because a one inch wire is too short for a
segment.

It seems to me that the center of the radials should be grounded for
lightning protection and that it will have no effect on the antenna
performance.

Comments please?

As someone who does a lot of V/UHF antenna design, I'd say that -20 is fine, and less than -20 is generally better if it doesn't screw up the whole pattern, which it seldom does. The aggregate of a lot of -20 is an average of less than -20 across the included angles. For EME, which is pickier than HF, it's fine. I'm not sure what Richard could be talking about.

Now if you want a 6 meter contest antenna for use in the midwest, you do not want very low sidelobes, but that's a different story.

Roger is wrong too, and Richard is not.

Electrostatic indicators don't measure current or charge movement, they measure voltage or charge displacement.

But what I really want to know is how Cecil can have current flowing both directions at the same instant of time in a single point of single conductor, can dismiss displacement currents as trivial things that can be ignored when they are required to define the most important aspects of transmission or antenna behavior, and say the very thing that is used to measure current suddenly doesn't measure his imaginary two-way reflected and forward current's vector sum.

That's what is really important, especially in light of the fact Cecil is quick to play superior.

Anyone who is really superior should be able to walk us through the physics of two-way current and tell us why dosplacement currents don't matter, and explain his magical transmission lines and antennas without displacement current in a way that we all understand.

You can't model a connection to ground except with the MININEC ground type, and that ground type isn't suitable when the model contains low horizontal wires as in a radial system. Therefore, there's no way in EZNEC to model a connection between a low radial system and ground. Any "connection" between the model radials and ground is solely by field coupling, not by ohmic contact. See The Modeling Ground chapter in the Building The Model section of the EZNEC manual for more information.

Another possible explanation is that if the main lobe is pointed in a
direction with low ambient noise (eg quiet sky), the last thing you
want to capture is significant power from hot earth (or other high
temperature sources) via minor lobes.

All the info in your paper catalog is available online at belden.com
. All the original poster has to do is click on " Catalog " , then the
" e-catalog " and then type in his cable type, (RG8X) in the search
window. Belden will then display the one type of RG8X cable they make,
their number 9258. If one then clicks on this number, the complete
specs will be displayed. Just scroll down the specs and one will find
the velocity factor of Belden's RG8X is 82%.

Cecil can't prove that charge can move in two opposite directions
at once. No one can. It's impossible. He's always had problems with
superposition, believing the constituents of a standing wave have
more reality than the wave itself.

A charge carrier cannot be moving in two directions at
the same time. Two currents can certainly exist in opposite
directions at the same time. That's what forward current
and reflected current is. If you want to deny the existence
of forward and reflected current, be my guest.

> This is precisely the current we would measure with a current meter

> sampling radiation, and it is the current that would determine phase of
> the radiation or induction field.

Yes, but if it's phase is unchanging, which direction is
it flowing? When the forward current and reflected current
are of equal magnitudes, which direction is the phasor sum
of those two currents flowing?

> So please expain to use, even if we allow a conductor to have TWO
> voltage gradients of opposite polarity over the same linear area of
> conductor, why Cecil's Current is important.

I have told you and W7EL about a dozen times before. One
cannot use standing wave current phase to measure the phase
shift through a wire or through a coil. Any such attempt
will fail. Yet, that is what W7EL has reported as technical
fact for about a year now.

> Also, tell us how we can measure and prove in a repeatable test, the
> two-way charge movement exists.

Please stop implying something that isn't true. There is no
two-way movement of single charge carriers. The current is NOT
the same thing as the charge carriers.

> Either you are creating diversionary conundrums, or you should be able
> to explain how we can have charges moving past a point in a single
> conductor that are moving both directions at one instant of time.

Please cut the BS, Tom. Individual charge carriers don't move in
both directions at the same time. The forward and reflected current

waves move in both directions at the same time, unaware of each
other's presence until they encounter an impedance discontinuity.

It is obvious that you don't understand forward and reflected EM
waves that can exist on a wire or even in free space. Please crack
open a textbook on such. Ramo and Whinnery is a good reference.

> The almost universal measurement method of current is magnetic.
> Suddenly Cecil's Theory of Current renders universal measurement

This is technical discussion and has absolutely nothing to do
with you or me.

> NEC uses current and voltage, not wave theory. You attempt to use an
> engine that uses what you say we can use to prove we are wrong in using
> current when there are standing waves!

How do you explain EZNEC getting the same answer as the distributed
network model at: http://www.qsl.net/w5dxp/travstnd.GIF? And while
you are looking at that graph, please explain how the flat phase
of the standing wave current can be used to measure phase through
a wire or a coil.

> Don't you think you should have understood the NEC engine used in the
> program before using it to prove we cannot use current without
> reflections?

No. EZNEC agrees with the distributed network model. That's all
I need to know about it.

> Yes, absolutely. If you don't understand that, you'd better review
> basic transmission lines and quit wasting everyone else's time giving
> assignments.

Exactly how does the displacement current to ground get outside
of a coax line with no common-mode currents?

> If we stopped that third path, the current would not change.

Assume one amp of forward current and one amp of reflected current
inside a piece of coax with no common-mode current. There's no
third path to ground, yet the standing wave still exists, with
current nodes and current loops. No third path to ground is
required.

> Answer the question Cecil, how can we have charge movement over a small
> length of conductor (in terms of the wavelength) in two directions at
> the same time, or a drift velocity in two directions at once?

Your straw man is noted for all the world to see. A single charge
carrier cannot move in two directions at the same time. But if
you are denying that two EM waves can move in opposite directions
at the same time, please just come right out and assert such.

In what direction is the RMS value of standing wave current flowing?

> Those wave currents could not travel at nearly the speed of light
> without the displacement currents.

You and I are talking about different displacement currents.
I'm talking about displacement current between a transmission
line and the ground. We had previously been talking about
displacement current between a loading coil and ground.

> Then you are silly. You cannot describe the reason for wave velocity of

I'll even say it again. Inside a piece of shielded coax, the
displacement current to ground is negligible yet the standing
wave still exists.

At points where those waves cause equal and opposite instantaneous
current, the standing wave current hits zero (is at a node). At all
other points, there is some net instantaneous current that is the
superposition of the current caused by the two waves at that point and
moment in time.

No. Current is the rate of charge movement. The charge cannot be
moving two directions at a point.

> That's what forward current
> and reflected current is.

Those are forward and reverse waves, not forward and reverse currents.
you are confusing the wave with the water.

> If you want to deny the existence
> of forward and reflected current, be my guest.

I deny it. There is only current at a point, just as there is only
water jiggling around under a wave on the ocean.

>> This is precisely the current we would measure with a current meter

>
>
> Yes, but if it's phase is unchanging, which direction is
> it flowing?

Phase doesn't indicate the direction charge is flowing (current is going). For both traveling waves and standing waves, charge sloshes back and forth with no average movement over a cycle. The phase of that movement just tells you how that sloshing is timed with respect to the phase reference. The only case where charge moves in one direction (unidirectional current) is DC.

> When the forward current and reflected current
> are of equal magnitudes, which direction is the phasor sum
> of those two currents flowing?

As long as you refer to waves as current, you are never going to get it. Waves travel on current reversals, but he wave is not current.

(snip repetition)

Forward and reflected EM waves, of course. Would you like to deny
the existence of the two waves in the following equation?

I(x,t) = I1*cos(kx+wt) + I2*cos(kx-wt) = Io*cos(kx)*cos(wt)

Your lack of math skills is really getting to be embarassing.

> ... can dismiss displacement currents as trivial things that can
> be ignored when they are required to define the most important aspects
> of transmission or antenna behavior,

The only displacement currents that I said were secondary were
the displacement currents to ground. In fact, in a shielded coax
with no common mode current, displacement currents to ground
are literally non-existent, yet the standing wave is still there
inside the coax, with its nodes and loops.

> ... and say the very thing that is
> used to measure current suddenly doesn't measure his imaginary two-way
> reflected and forward current's vector sum.

I didn't say that. I said the standing wave phase cannot be used
to measure the phase through a wire or a coil. That is readily
apparent at: http://www.qsl.net/w5dxp/travstnd.GIF which you
have been avoiding like the plague.

The phase information is there in the standing wave current, but
it is in the magnitude, not the phase. And you have to understand
arc-cosine functions to be able to extract that phase information.

> That's what is really important, especially in light of the fact Cecil
> is quick to play superior.

"Play superior"??? I'm not the arrogant one claiming to be so
omniscient that he is never wrong.

> Anyone who is really superior should be able to walk us through the
> physics of two-way current ...

Already done - please reference the above web page. All the data
is exactly what EZNEC reported. I can lead you to water but I
can't make you drink. If you will tell me what you don't understand
about that web page, I will walk you through it, step by step.

Hi Roger,

Yes, I understood. And from your reference:
"The electrostatic meter movement is actually a large variable capacitor in which one set of plates is allowed to move. The movement of the plates is opposed by a spring attached to the plates. A pointer that indicates the value of the voltage is attached to these movable plates. As the voltage increases, the plates develop more torque."

When a current is applied to a capacitor (aka voltage applied, but as we all know, a current moves charge to those plates), there is a force developed between the plates (actually in the dielectric) which is tangential to the plates. This force has the tendency to eject the dielectric. Our usual experience with capacitors is we rarely have enough charge AND enough capacitance to measure this effect.

By making one plate movable, the force of the current flow is expressed in the movement of that plate against a spring (the exact analogue of opposing magnetic fields, one fixed and the other imparted by a continuous current flow).

"To develop sufficient torque, the plates must be large and closely spaced."

That necessary condition of high capacitance; and

" A very high voltage is necessary to provide movement, therefore, electrostatic voltmeters are used only for HIGH VOLTAGE measurement."

enough charge to reveal the force.

Your reference is actually

********** W R O N G !! or at least incomplete **********

because what it is describing with two plates in repulsion is NOT a capacitor (at least not in the conventional sense). This is because the two plates share the same charge (because they are the same conductor), hence the repulsion. Further, as this is a variant on the Leyden Jar, there is another true capacitive plate either in the

nearby structure, or the earth. Otherwise there is no reason for the charge to flow there in the first place.

I agree with you. That topic is just another straw man from
W8JI who is afraid to discuss EM waves moving in opposite
directions at the same time. It's the EM waves that are
moving in opposite directions at the same time, not the
individual charge carriers.

I have seen waves flowing in and flowing out at the same
time in the Pacific Ocean. That doesn't mean that individual
water molecules are moving in two opposite directions at once.

Doesn't it mean you are losing the argument when you have to
make up false stories about what I have said?

>
> In what direction is the RMS value of standing wave current flowing?

That's easy. RMS current is an AC measurement of current along the
conductor. Over any integer number of cycles, the total movement of
charge is zero. The current spends half the time going one way, and
half the time going the other way. This applies to both standing and
traveling wave induced currents. The only current that describes a
net movement of charge in a single direction is DC.

>> Those wave currents could not travel at nearly the speed of light
>> without the displacement currents.
>
>
> You and I are talking about different displacement currents.

If the transmission line is a center conductor in a grounded shield,
then that is what I am talking about. If the transmission line is
balanced, then the displacement current is mostly the current between
the two lines.

> We had previously been talking about
> displacement current between a loading coil and ground.

That's also included in what I am talking about. Ant current caused
by a voltage swing in a conductive surface along the wave path is
included.

>> Then you are silly. You cannot describe the reason for wave velocity
>> of a conductor, transmission line or EM wave without displacement
>> current.
>
> How does the displacement current get to ground when it's
> inside a shielded piece of coax with no common mode current
> on the outside braid?

The shield is the ground potential for the center conductor. If you could mount a tiny current pickup loop between the center conductor and shield, surrounding nothing but the coax dielectric (so you could look through the hole, if you were an observer on the center conductor), that pickup loop would measure a current if there is any voltage wave on the center conductor. That is a displacement current.

>> Displacement current into the space around the node.
>
>
> How does the displacement current get past the coax shield
> to the outside world?

As far as the center conductor is concerned, the shield is the entire universe.

>> So please stop saying that displacement current is negligible in some
>> cases of traveling or standing waves.
>
>
> I'll even say it again. Inside a piece of shielded coax, the

You have a blind spot as to where there is current in a coax. Do you deny current through any other capacitor that has voltage swing across it? Then why deny that the capacitance between the center conductor and a carefully surrounding grounded surface separated by a dielectric conducts current when there is voltage swing on the center conductor?

If the coax carries a standing wave, then at the points on the center conductor that are current nodes (for current along the conductor) the capacitive current to the shield is at its peak, because that is where the voltage peaks of the standing wave occur.

Those two expressions describe patterns of current over time and location that produce current in each direction half the time (except at nodes, where the current is zero).

The amplitude of a current cycle is constant for the first one (traveling wave), but the phase differs at different locations (by the amount of kx).

The amplitude of current cycle described by the second one (traveling wave) varies with location, and the phase has only two possibilities (one when cos(kx) is positive and 180 degrees different when cos(kx) is negative). But in both cases, current at any point reverses twice a cycle (cos(wt)) and charge goes nowhere over a cycle.

Well, that means denial of the distributed network model.
I've been waiting for that to happen. There's no point
continuing an argument with someone who denies one of
the cornerstones of EM wave theory.

The distributed network model is accepted as a superset
of the lumped circuit model and works when the lumped
circuit model fails.

The fact remains that standing wave current phase cannot
be used to measure phase delay through a wire or through
a coil. There is no phase information in standing wave
current phase.

But from the concept of a standing wave producing a current distribution along the center conductor, the shield performs the function of ground. One current path is along the center conductor (in one of two directions) and the other current path is through the dielectric to the shield, in proportion to the rate of change of voltage at any point on the center conductor.

If you eliminate the shield and have a single wire carrying a standing wave over a distant ground, the capacitance per foot drops (raising the characteristic impedance of the transmission line, and losing energy to EM waves, but the displacement current is still there in proportion to the capacitance per foot and the rate of charge of voltage. There is nothing inherently different. Only the loss and ratio of L/C per foot changes.

But that is irrelevant. The relevant fact is that there is NO
third path to ground yet the standing waves exist anyway.

That seems to indicate that the displacement current path
to outside world ground is a secondary consideration compared
to the superposing of the forward and reflected waves.

If you are prepared to reject the distributed network model,
are you also prepared to reject Maxwell's equations?

Please note that rejection of the distributed network
model leaves you with only a model known to fail under
certain conditions.

In any case, you haven't explained how the unchanging
phase in a standing wave current can be used to measure
phase shift through a wire or a coil. EZNEC says it
is not a valid approach at:

There is only water juggling under two or more waves in the
ocean. Anyone who has stood on the beach has observed ocean
waves moving in opposite directions.

Your assertion is easy to disprove. In the following example,
the two sources have identical outputs and are phase locked.
They are each equipped with circulators and 50 ohm loads.

Source1---------------50 ohm coax------------------Source2

There is current flowing from Source1 heating up Source2's
load resistor to the tune of I1^2*R. There is current
flowing from Source2 heating up Source1's load resistor
to the tune of I2^2*R. Your denial seems to be a denial
of reality and more of a religious gut feeling than anything
else.

If you disconnect Source2 completely in the example above
the conditions will be the same except Source1 will be
dissipating its own power after a round trip to the open
end and back by the energy waves.

Incidentally, in the double source example above, which
direction is the standing wave current flowing? How could
its unchanging phase be used to measure the electrical
length of the coax?

Please don't be silly. Distributed networks have points. An infinite
number of them. Calculus is used to smoothly move through this
infinity of points. But at any particular point, current is defined
as the rate of movement of charge past that point.

> I've been waiting for that to happen. There's no point

So you deny that there are any points (where voltage can be defined or
that charge passes) in all distributed networks?
How strange.

> The distributed network model is accepted as a superset
> of the lumped circuit model and works when the lumped
> circuit model fails.

Yes. And distributed networks are made of a continuum of points.

> The fact remains that standing wave current phase cannot
> be used to measure phase delay through a wire or through
> a coil. There is no phase information in standing wave
> current phase.

Yes. That fact remains.
It is a non sequitur in the above discussion, however.

That the standing wave current cycle has the same phase along a half
wavelength of conductor has nothing to do with the current through
that conductor having a point definition (the x in the standing wave
function you keep displaying). And at any point the current is AC,
spending half of the time going one way, and half of the time going
the other way (the positive and negative parts of the cycle in time,
defined by cos(kx)*cos(wt), once you pick and x.

To the center conductor, carrying the standing wave, the shield is the outside world. If there is no shield, the outside world is the outside world, as far as displacement current goes. Do you imagine this current changes in some way other than magnitude and wave velocity when you wrap a shield around a wire carrying a standing wave?

> If you are prepared to reject the distributed network model,
> are you also prepared to reject Maxwell's equations?

I am prepared to do no such thing. I am explaining distributed network theory to you.

> Please note that rejection of the distributed network
> model leaves you with only a model known to fail under
> certain conditions.

Just because I talk about current and voltage at points does not mean I am limited to lumped (idealized) networks. Distributed networks are made of points, too.

So waves can move in one or more directions while any bit of water
moves only locally. Same with charge.

> Your assertion is easy to disprove. In the following example,
> the two sources have identical outputs and are phase locked.
> They are each equipped with circulators and 50 ohm loads.
>
> Source1---------------50 ohm coax------------------Source2

Got it.

> There is current flowing from Source1 heating up Source2's
> load resistor to the tune of I1^2*R.

There is energy heating the load resistor. The current does not come
through the source. It is created at the end of the line by the
traveling energy wave. The charge that makes up the current passing
back and forth through the load to produce the heat does not come from
the source. It comes from the load itself and and the nearby part of
the line (within less than a 1/2 wavelength). That charge is caused
to move by the energy in the wave.

> There is current
> flowing from Source2 heating up Source1's load resistor
> to the tune of I2^2*R.

No, for the same reason. The current is local to the end of the line
near the load. It is not current that travels the length of the line
from source to load, but the energy in the wave, just as the water

from the underwater landslide is not what washes up on the beach a
hundred miles away. Local water is pushed up on the beach by the
energy in the traveling wave that connects the landslide with the beach.

> Your denial seems to be a denial
> of reality and more of a religious gut feeling than anything
> else.

My denial is a recognition that current does not connect the source to
the load, traveling energy waves do, however. Local current carries
that wave along the line.

> If you disconnect Source2 completely in the example above
> the conditions will be the same except Source1 will be
> dissipating its own power after a round trip to the open
> end and back by the energy waves.

Yes, its wave energy will return to the source and cause current local
to the source to pass through that load.

> Incidentally, in the double source example above, which
> direction is the standing wave current flowing?

At any point that is not a node, back and forth, every cycle. At
nodes, back and forth across the dielectric of the line.

> How could
> its unchanging phase be used to measure the electrical
> length of the coax?

You measure the difference of the node positions, with and without the
coil. The shift in distance (in wavelengths) between the two nodes
that straddle the coil is the phase shift of the coil for each of the
traveling waves that make up the standing wave.

I see that Cecil is still having trouble with RMS, as well as with current. Otherwise he couldn't have come up with the nonsense question

>> In what direction is the RMS value of standing wave current flowing?

The RMS value of current doesn't flow. Charge flows, and current is the rate at which it flows. RMS is one way of expressing the magnitude of a time-varying current. In a steady state environment of pure sinusoidal waveforms, any current can be expressed as Ipk * cos(wt + phi) where Ipk is the peak value of the current, w (omega) is the rotational frequency, and phi is the phase angle. This gives you precisely the value of current at any instant in time, t. You can equally well express it as Irms * cos(wt + phi) where Irms is the RMS value of the current. Nothing is lost or gained by choosing one convention or the other, and using RMS doesn't require abandoning the time varying or phase information. (In EZNEC I chose to use RMS; NEC uses peak. They differ only by a constant factor of the square root of 2. Both report phase angle along with amplitude.) In either case, if you know or assume w, the current at any instant is known if you know phi and either Ipk or Irms.

A point of clarification to John's posting:

When a standing wave exists on a transmission line, the phase of the voltage or current is fixed (other than periodic phase reversals) with position only if the end of the line is open or short circuited. Otherwise, the phase of voltage and current will change with position.

==========

For coax, Zo = 60 * VF * Ln(D / d)

So Zo varies as VF varies.

You'll just have to measure VF or Zo.

Similar for attenuation.

Reg.

Yuri,

Part of communicating is understanding the words the other person is
using. I'm only trying to understand what you intend the words you use
mean.

Please don't blame me for trying to sort out what you are saying. If
you mean "reactance", say "reactance" and not "impedance". If you mean
"through", say "through" and not "across".

When you use "across", I guessed and thought you really meant "through"
or "at each end".

When you used "impedance", I couldn't guess and figure out if you meant
the scalar impedance, vector impedance, resistance, reactance, or what.
It could mean too many things.

Cec,

Alternatively, place orders for one or two reels of coax with all USA, Japanese, Chinese, Korean, German, French, Russian, British cable manufacturers.

When your back yard is stacked high with full cable reels, cut off a measured length of cable from each real, lay them in straight lines on the ground and measure the velocity factors using a hand-held antenna analyser at around 10 MHz. You will also need a good steel measuring tape and a sharp cable cutter. Don't use an axe!

Discard outliers of the distribution - they are probably faulty. Use your pocket calculator to find the average, max and min, and the standard deviation and you will have the answer to your question.

Then set up a shop.

But I'll save you the trouble and make an uninformed guess. The Standard Deviation will be around 4 percent of the VF with the 3-Sigma limits at plus and minus 12 percent.

Reg.

AK wrote:
> Is 78% the correct velocity factor for RG8X coax?

NO.

RG-8X is really not an RG cable, and has no manufacturing standard.

Foamed cables can vary from near .7 vF all the way to near .9 vF

The manufacturer normally adjusts the ratio of air to dielectric to get the correct impedance. Since RG8X has no standard dimensions or conductor diameters, and it has no standard impedance range, the vF will vary all over the place.

RG8X is normally a much denser foam (less air) than other foam cables. The RG8X cable I have is in the low .7 range as measured on a network analyzer. I've never found any with higher than the upper .7 range.

Since there is no manufacturing standard (meaning it is NOT really suitable for an RG number) you should measure the cable.

> ....---> ---> --> -> <- <-- <--- <--- <-- <- -> -->......
> hole--------------------50 ohm coax--------------------hole
x y
There is a standing wave current node at 'x' and a standing
wave current antinode (loop maximum) at 'y'. Let's say we
installed coils at those two points

....---> ---> --> -> <- <-- <--- <--- <-- <- -> -->......
hole--------------/////----50 ohm coax----/////------hole
x y
Now we have current flowing into both ends of the coil
located at 'x' and current flowing out of both ends of
the coil at 'y'. How does the lumped circuit model handle
that situation?

Continuing with this posting:
> Please don't be silly. Distributed networks have points. An infinite
> number of them. Calculus is used to smoothly move through this infinity
> of points. But at any particular point, current is defined as the rate
> of movement of charge past that point.

No argument, but that is instantaneous current and that is NOT
the subject of this discussion. We are discussing the RMS phasor
value of current used by W8JI and W7EL for their measurements
and reported by EZNEC as in the graphic at:

http://www.qsl.net/w5dxp/travstnd.GIF

Please look at the standing wave current phase and tell us how
that flat phase curve can be used to measure the phase shift
in a wire or coil.

The current reported by EZNEC and measured by W8JI and W7EL is
NOT instantaneous current. It is RMS current. Instantaneous
current is completely irrelevant to this discussion.

>> I've been waiting for that to happen. There's no point
>> continuing an argument with someone who denies one of

:-) You have your points confused. I was talking about a logical
point. Here, let me translate for you. There's no *reason* to
continue an argument with someone who denies one of the
cornerstones of EM wave theory. John, is English your native
language? For the record, I did NOT deny the existence any
physical points!!!

>> The fact remains that standing wave current phase cannot
>> be used to measure phase delay through a wire or through
>> a coil. There is no phase information in standing wave
>> current phase.
>
> Yes. That fact remains.
> It is a non sequitur in the above discussion, however.

Whoa there, John, it is the entire reason for this discussion.
W7EL used that standing wave current phase to try to measure
phase shift through a coil. If there is no phase information
in standing wave current phase, then his entire argument
falls apart and he is back to square one with his flawed
lumped circuit model.

Why insulate radials that are lying in or on the ground?
What would that do?

If you insulated them, why would you then ground them with a rod?
Why not just use bare wire and be done with it?

Why would you use a model, when the model makes many assumptions about
the earth that likely are not true for your particular soil?

I guess what I am asking is what you are trying to learn or trying to
do?

> a shield around a wire carrying a standing wave?

No, that is your point, not mine. My point is that displacement
current to real ground is non-existent outside of a coax shield
(unless common mode current exists) and that it is usually a
secondary effect if the coax shield doesn't exist. The primary
reason for the variation in standing wave current along the line
is the phasor sum of the forward and reflected wave phasors that
are rotating in opposite directions. Do you understand phasor
addition? 1 at zero + 1 at 180 deg = zero at a standing wave
node? Displacement current to real ground doesn't cause that.

> I am explaining distributed network theory to you.

:-) How? By denying the existence of the individual H-fields
in forward and reflected EM waves? Now, that's really funny.

>> http://www.qsl.net/w5dxp/travstnd.GIF
>
> And I have agreed with that. Why do you keep bringing it up?

Because that's the whole point of this discussion. If you
agree with that, there is no reason to continue. I just
don't care about instantaneous current, Brownian motion, or
the exact location and velocity of every electron carrier.
There's too much uncertainty involved.

All the info is very interesting. Thanks folks.

Just want to make two 50-ohm 1/4-wave section lengths to transform the impedance of two linear-loaded 40 meter verticals (spaced 1/4 wave) from around 32 ohms to about 75 ohms, and then extend the cable from the "director" vertical element with another 1/4-wave with 75 ohm coax for the 90/90 phasing. Then I just "tee" the two feedpoints together to get one common feed point that's close to 50 ohms. Have done this previously with good results, and had a much better than expected match to the 50-ohm transmitter feedline. The last time I did this, I used fence wire that was staked into some flat farmland turf for the ground system. This time I will have to create an artificial ground plane or counterpoise, as the present mountain terrain does not lend itself well for creating a good low-loss real-ground system. Still have my old RG-11 matching section for the one 75-ohm coax 1/4-wave extension cable, but the two RG-8 sections are no longer around. So, thought I would use the smaller and cheaper RG8X this time. Maybe I won't. HI

My point exactly. I'm glad you agree.

> There is energy heating the load resistor. The current does not come
> through the source. It is created at the end of the line by the
> traveling energy wave.

The H-field energy in the load originated in the source. Current
is directly proportional to the H-field in the EM wave. Let me
quote Ramo and Whinnery:

I = e^jwt/Z0[(V+)(e^-jwz/v) - (V-)(e^jwz/v)]

This is the *continuous* equation for source current at
z = 0 and load current at z = (distance). Essentially the
same equation is found in every reference on transmission
lines.

They don't say current is "created" at the load. They say
current is a *continuous single-valued function* between
source and load. Do you have a reference for your "creation"
of current?

That the H-field experiences a delay and transformation on its
way to the load doesn't mean that current is magically created
out of thin air at the load.

Hang some modulation on the current at the source. You will
measure that modulation arriving at the load in the form of
current exactly in accordance with the laws of physics
embodied in the distributed network model.

In a DC circuit, is the current also "created" at the load?

> My denial is a recognition that current does not connect the source to
> the load, ...

Then by all means, disconnect the source and keep the current.
Anything is possible in your mind. Just don't expect that to
work in reality.

hi

i've noticed a few installations of say a 2m beam vertically mounted to
a regular metal tv style mast

from looking at it, you have the mast(metal) going between 2 elements
and longer than the elements

so i was wondering as this is a common mounting style and method

how bad is the beam pattern for rx and tx ? effected by the metal mast?

it also got me thinking i've noteced some beams as in the above use a
fiberglass boom while others use metal

how does this effect patterns and efficiency

both from a practical point of view and technically speaking

???

thanks

Of course, I1=I2 is the definition of a standing wave
which is the topic of this discussion. Any current left
over is traveling wave current, by definition.

The concept is akin to the separation of differential
current from common-mode current. Differential currents
are equal by definition.

Standing wave component currents are equal by definition.

The metal mast affects the performance to some degree, but I don't
know of a rule of thumb for predicting it. So the answer is, it
depends.

A fiberglass or other non-metallic mast will help, it you also use a
non-metallic coax line.

I am in prototype mode.
I am trying to validate what I think I know.

These prototypes I put together are not intended to last beyond the test stage. That allows the luxury of some pretty primitive mechanical conditions.

At the moment I have three 25 foot electric drop cords in service as ground radials. I am using a 28 foot (approx) vertical radiator. There is a series load inductor (tapped) of about 130 micro henrys.

I am testing with 100 watts or less and I have an MFJ-269 to work with.

I live on a slight ridge in Central North Carolina and I take a lot of lightning strikes.

I am tinkering with this kludge as a "lab project" trying to get a better understanding of short verticals. I don't really expect to find anything new.

Cecil,

The wave is stationary. The current is not. It is as simple as that.

Distinctions between *at* and *flowing* are meaningless. Current is what it is, and mere words don't change anything.

You seem to be reduced to arguments about semantics, which is both good news and bad news. The good news is that there does not appear to be any disagreement about the physics. The bad news is that the argument will never end.

He seems to confuse energy in the wave traveling along a conductor
with the current it induces along that conductor, as it travels. I
have had a few such mental blocks and made a fool of myself a couple
times because I was sure I was right. But when the light finally came
on, lots of related things suddenly crystallized in my mind and I
jumped to a better understanding. One of my regrets is that I didn't
go back and apologize to my 7th grade science teacher for arguing with
him with so little tact, when I found out a year later that he had
been right and it was I who had been laboring under a misconception.
Same thing happened, on a different topic, in 8th grade science. So I
think I understand his attitude. I just hope that he sees that my
intentions are honorable, in this discussion. I am not attacking him,
but working for his understanding. I may be mistaken and end up
having another seventh grade moment here, but I'm not trying to
embarrass him.

Is that because the result is not a pure standing wave (superposition of two equal and oppositely traveling waves), but a superposition of a pair of traveling oppositely traveling waves of different amplitudes?

-20 dB from a transmit point of view means that 99% of your radiated power is going in the forward [desired] direction. That's GOOD!

From a receiving point of view, -20 dB means that an undesired signal from the side or back of the antenna is approximately 3 1/2 S units [-20 dB] from it's maximum value. It is easily conceivable that you may be trying to copy a weak barely detectable signal from your desired direction and be unable to copy that signal because of a stronger signal that happens to be in a side lobe and on or very close to your frequency. That's NOT too GOOD :-(

For most practical Ham antennas in the DX or contest mode a -20 dB sidelobe is adequate. You can spend a lot of $$$$ buying antennas with better side lobe specifications. You are the only one who can decide if the benefit to your operations is worth the expense.

For VHF/UHF EME work you really want the best side lobe and F/B ratio [front to back] performance you can buy, primarily to minimize undesired signals from the non preferred direction.

> that situation?

If we assume the coil is an idealized lumped inductance with no stray capacitance at all (not a real inductor) then it would have the same instantaneous current at each end and that current would be zero, since it has zero size. In other words it would fit entirely in the point that holds the node.

Real inductors with stray capacitance and imperfect magnetic coupling for all parts of its internal current path, would have a phase shift in the current at opposite ends, so they would have current at their ends that was 180 degrees out of phase, if they were centered on the node points. For half of each cycle, current would be entering each end, and for the other half of each cycle, current would be leaving each end. Both those currents would detour out the sides f the inductor into displacement current through the stray capacitance of the surface of the inductor to its surroundings.

I think (with very little actual knowledge of the software) this conceptual model is how EZNEC handles current through a modeled inductor and how it can have different currents at the inductor ends, without being aware of whether those currents are driven by traveling

or standing waves. It is all based on current through inductor
segments and voltage across capacitive segments. If the segments are
small enough, it is a good approximation of a distributed solution.

I am not arguing this point. RMS values capture the amplitude of a
cycle of variation. I am inside the cycle. But the two views are
consistent.

According to you, you are finished talking about coils, and want to delve strictly into wave concepts. To honor your request, I have tried to keep the discussion general, and avoid bringing up the effect on and measurements of coils. But, in this post, you talk about almost nothing else but coils. I get the distinct feeling that you want to win a debate far more than you want to reach an understanding with no internal contradictions. And you are willing to use dishonest debate tactics (like telling me not to discuss a topic with you, and then telling me that that exact topic is "the entire reason for this discussion". Do you get beat up a lot in face-to-face arguments?

> W7EL used that standing wave current phase to try to measure

> in standing wave current phase, then his entire argument
> falls apart and he is back to square one with his flawed
> lumped circuit model.

Yes. But I cannot concede that point of discussion for someone else. Are you going to hit me over the head with this till every person in the World agrees with you? I am trying to think the general case through with you.

In case you don't realize, there is more than one person out here, responding to you.

You remind me of a type of insanity where the sufferer thinks that everything he is experiencing an organized illusion by a single offending intelligence (you against the Matrix) bent on forcing him to think that a lie is the truth, regardless of who or what he deals with. Everyone he meets, every apparently random happenstance, the actions of his dog and the weather, generally, are all a conspiracy to force him to think that black is white, and he isn't going to fall for it.

If you cannot carry on a conversation with more than one person at a time, and treat each of them as a separate mind, then this is the wrong venue for you.

I am making the point that if the displacement currents were
insignificant, outside a coax, then the speed of light for waves out
there would be infinite. And they are not, therefore those
displacement currents cannot be assumed to be insignificant.

>> I am explaining distributed network theory to you.

> the exact location and velocity of every electron carrier.
> There's too much uncertainty involved.

You are avoiding the very facts that would allow you to make an air tight argument for your beliefs about "the whole point of the discussion". You somehow picture current as a continuous thing from one end of a conductor to the other, when it carries a traveling energy wave. This is a misconception.

You appear to accept that current is a localized kind of thing (parts of the conductor carry current, but those parts are separated by nodes) when two traveling waves going in opposite directions superpose, but have no concept that explains how this happens, only a mathematical function that quantifies it.

What you don't get is, that the currents that each of those traveling waves would have generated were localized, to begin with. Local current cycles and voltage cycles are the water the energy waves ride on over arbitrarily long distances along conductors and transmission lines.

I know you don't care about this factoid, but understanding it would allow you to think about "the entire reason for this discussion" much more clearly.

> John Ferrell W8CCW

Insulated radials on the ground still have significant capacitive
coupling to the ground. This coupling also depends on conditions
unique to your location. These two factors alone will make any form
of modelling null and void. When radials are raised above ground
level the height above ground should be taken into account as well.
If you have a vertical at ground level you would do better to have
a reasonable number of radials laid along the ground, and the
length need not extend beyond the height of the vertical element.

>
> I = e^jwt/Z0[(V+)(e^-jwz/v) - (V-)(e^jwz/v)]
>
> This is the *continuous* equation for source current at
> z = 0 and load current at z = (distance). Essentially the
> same equation is found in every reference on transmission
> lines.

Yes. That equation describes the instantaneous current you would find
at any point as the wave pases through it.
It does not imply that the current at one point is the same current at
another point. It implies a continuity of the energy wave. At some
points along that wave, the current has some positive value (charge
going in the same direction as the wave. At other points, the current
has some negative value, indicating that charge is moving the opposite
way from the wave direction. The current is continuous only in that
there is a smooth, sinusoidal variation in its magnitude and direction
as you look along the wave path. but the current at one point is not
the current at some other point.

> They don't say current is "created" at the load. They say
> current is a *continuous single-valued function* between

> source and load.

A current described by a continuous single valued function is not a
continuous current. The water that drowns people in a tidal wave in
California is a current dragged over the beach by an energy wave that
caused a continuous pattern on of local currents from the landslide in
Hawaii. But the actual water current (movement of water molecules
carrying the wave energy) did not flow continuously from Hawaii to
California. There are no Hawaiian fish carried to California by a
current of water that connected those two locations.

> Do you have a reference for your "creation"
> of current?

Only Maxwell's equations.

> That the H-field experiences a delay and transformation on its
> way to the load doesn't mean that current is magically created
> out of thin air at the load.

Current is created and reversed (charge is sloshed back and forth) all
along the line, from source to load. Just as water is moved up and
down all along the path of a wave over the surface of the water. But
if you pick any bit of water, it does not follow the wave.

> Hang some modulation on the current at the source. You will
> measure that modulation arriving at the load in the form of
> current exactly in accordance with the laws of physics
> embodied in the distributed network model.

Yes, delayed by the speed of light in that medium.

> In a DC circuit, is the current also "created" at the load?

No. DC has an infinite wavelength, so there is no significant
distance (in wavelength units) no matter how far apart the source and
load appear to be. If a battery near earth is connected to a load
near Alpha Centauri by a perfectly conducting loop, and you consider
the DC case (DC has an infinite duration), then there is no
significant distance between that source and load, so local current
connects them. Electrons that are pushed out of the battery will
reach the load and return to the battery. The definition of "local"
is wavelength dependent.

Back to the RF case: Do you imagine that electrons from the source
reach the load?

>> My denial is a recognition that current does not connect the source to
>> the load, ...
>
>
> Then by all means, disconnect the source and keep the current.

Be happy to. For the amount of time it takes for a wave to pass the
full length of the line, energy will continue to be delivered to the
load (current will pass through it), even though the source has been
disconnected and causes no further current in the line.

> Anything is possible in your mind. Just don't expect that to

On the contrary, Gene. The disagreement is whether W7EL's use of standing wave current phase to try to determine phase shift through a coil was valid or not. That is the present point of disagreement.

I have posted what you said many times but W7EL doesn't read my postings. So would you kindly point out to W7EL that there is no phase information in standing wave current phase?

708. 16 el coaxial colinear (2.4ghz) question

Newsgroup: rec.radio.amateur.antenna
Date: 2006-04-09 17:45:06 UTC
From: Ken Bessler <kg0wx@NOSPAMyahoo.com>
Message-ID: <LKb_f.551$B42.142@dukeread05>
Source record: 61250

I built this antenna expecting better performance from my WiFi
setup. Stock antennas are 1/2 wave verticals at the back of the
router. New antenna is a 16 element coaxial collinear @32' agl.
Total transmission system losses work out to 5.299db @2.412
ghz (includes feedline + N connectors).

So, why does this antenna only have about (rough measurement)
1-3 db gain over the stock antenna? I was meticulous in my work,
measuring the antenna parts with a digital caliper and checking
the connections with a DVM along the way.

Maybe my design is a fault? I built the antenna just like this:

http://wireless.gumph.org/content/4/3/011-mini-wireless-antenna.html

Except in my version, I've got 16 elements made from RG58. I also
made 2 four element antennas for the back of my thinkpad and they
seem to be working about twice as far as the antennas they replaced
(inverted V's).

Any ideas?

John Popelish wrote:
> He seems to confuse energy in the wave traveling along a conductor with
> the current it induces along that conductor, as it travels.

It's not confusion, John. It is engineering convention. Every engineering reference book I have refers to current flow at one point or another. Most of them also refer to power flow. "Transmission Lines and Networks", by Walter C. Johnson even refers to "The Conservation of Power Principle". Since there is no such thing as an RF battery, we know exactly what Mr. Johnson meant.

You are discussing the conventions used by physicists. Since this is basically an RF engineering convention newsgroup, you need to adjust your concepts accordingly or tell everyone that you are nit-picking based on the conventions from the field of pure physics.

In the engineering world: Power companies generate power and transfer the power to the consumers over transmission lines. RF transmitters generate power which is transferred over the transmission line and radiated by the antenna.

There is always a convention for placing an arrow on a wire to indicate direction of current flow, whether RMS AC or DC or RMS RF. The AC conventions are left over from the DC conventions. If you are trying to change those conventions, please say so.

Food for thought: If an electron can pass through two different holes at the same time, can it also travel in two directions at the same time? Quantum physics says that is a possibility.

> Is that because the result is not a pure standing wave (superposition of
> two equal and oppositely traveling waves), but a superposition of a pair
> of traveling oppositely traveling waves of different amplitudes?

Yes, but the definition of a standing wave is that the two waves are of equal amplitudes. The wave you are describing is a hybrid wave containing both a traveling wave and a standing wave. Any real-world system contains hybrid waves in various ratios of traveling waves to standing waves.

Hi Ken,

What did you compute as being the Velocity Factor for the shield being
covered with thick PVC?

The problem with this modified Franklin Array is that you are cutting
for half-wave dimensions once, for two Velocity Factors along the same
length. Only one is going to be correct, and it is going to impact
the theoretical application of the other.

You might want to try again using bare wire, twin lead fashion.

IMHO, hardly anyone here on r.r.a.a is interested in technical facts.
Most "experts" think they already know everything, wouldn't recognize
a differing concept if it bit them in the arse, and are more dedicated
to preserving the pecking order than anything else. 'Course, I am only
human and could, therefore, unlike the omniscient experts, be wrong
about that.

But I am not talking about displacement currents within the
transmission line, as exists in free space. I am talking *solely*
about the displacement currents to *earth ground*. I contend that
those are often secondary effects as proven by the coax example.
Just how much displacement current to "earth ground" is there for
a coil located halfway between here and Alpha Centauri?

> Exactly the opposite. I am explaining the distributed effect of the E
> field along the wave.

And completely ignoring the H-field? In the treatment of those fields,
the only variation is Z0. For EM fields, there is no "across" and no
"through". The difference between voltage and current essentially
disappears except for their Z0 ratio. The equation for current in
a transmission line is identical to the equation for voltage except
for the Z0 term. Current "drops" are commonplace in lossy transmission
lines.

For instance, what is the current at the end of 200 feet of RG-58
terminated by a 50 ohm antenna used on 446 MHz when the source
current is 2 amps?

> You are avoiding the very facts that would allow you to make an air

Maybe in the field of physics - not in the field of RF engineering.
For any two current points, I can calculate a point in between.
Sorry, but that's a characteristic of a *continuous* single-valued
function and can be proven mathematically. I admit to being a EE/math
major. I didn't take many pure physics courses so I am missing your
point about me being able to prove anything additional. Maybe it
will dawn on me after awhile.

> What you don't get is, that the currents that each of those traveling
> waves would have generated were localized, to begin with.

I realize that is the physicist talking and it agrees with my
earlier assertion that standing wave current doesn't flow. I

guess I'm so dense that I need help in proving what you think
I can prove with that information. Right now, I am apparently
missing something, maybe because of too much California Merlot.

To Ken

Hi Ken, I'd always take Richard's advice before mine. But, I wonder if
you realize how difficult your task is. It is a very difficult project to
develop the design of any array of radiators thats about 5 wavelengths long.
And, it *is* a project, not just a matter of precise measuring and cutting.
I'd think that 3 dB improvement over the antenna that was designed for
optimum performance shows that you are doing something right.
This project is a great learning opportunity for you.

I'd suggest that you get a directional coupler and get some idea of the
match of the array while it is being made longer. If you can manage to keep
the VSWR under 2:1 with 6 or 8 elements, at your operating frequencies, you
will be way ahead of me.

Maybe for DC. But depending upon the length of the transmission
line, probably not for HF RF. Is that a rhetorical question?

Everything. That's what this thread is all about. I will repeat:

Can the standing wave current phase, with its unchanging phase,
be used to measure the phase shift through a wire or coil?

That's the admittedly narrow present topic. The answer is either
'yes' or 'no'. After we answer that narrow technical question,
the discussion can procede.

I just did. I hope you realize that anyone is perfectly free to
ignore anything posted to this or any other newsgroup, and long as it
pleases them. If you are going to have trouble sleeping because you
can't get complete agreement from everyone who you have ever seen post
to this group, your problems are a lot bigger than coils and waves.

>> I am not arguing for the validity of that measurement. Argue about it

That is their prerogative. Deal with it. I am putting considerable
effort to understand the physics of the situation and to share my
thoughts with you. If this is no interest to you, I will discuss this
interesting topic with someone else.

>> In case you don't realize, there is more than one person out here,
>> responding to you.
>
> Please forgive me for not recognizing which of the ten individual

> a differing concept if it bit them in the arse, and are more dedicated
> to preserving the pecking order than anything else. 'Course, I am only
> human and could, therefore, unlike the omniscient experts, be wrong
> about that.

And that is exactly why I have refrained from personal attacks (though
I have indulged in a few observations as above, because I think
considering them might open your eyes to how you appear to others, and
how that interferes with your arguments. So even those observations
were not made in an attempt to win an argument with you, but to assist
you in thinking more clearly.

For the most part, I have tried to talk about physics, not pecking
order or personalities. But you keep cutting me off, saying you are
not interested in physics, but in winning a debate with a few people,
regardless of who you have to insult to win.

At this point, my mental model of how your mind works is just about as
interesting to me as my mental model of how EM waves work. The
universe is full of strange and fascinating processes. But if you get
back to physics, I will soon lose interest in your mind.

Source record: 61270

Hi Ken

My first thought would be that a collinear with such a high gain would have a very narrow vertical beamwidth. ie a small angle off the vertical where mounted would have the remote site some dB down off the main lobe. The test for this will be to tilt the antenna back and forth whilst checking the RSL. Also keep in mind that reflections on 2.4GHz will cause a similar picket fence effect you might have heard on 2m/70cm. Your antenna could be mounted in a semi null. (I might try and model this some day and post you the results)

Next idea is that with such a long colinear you are getting losses along the coax elements to the point where the upper element is radiating less than the lower ones. This will cause some skew in the radiation pattern. (upward tilt) TG213 would have been a better choice for this many elemets for this reason.

Thirdly... Although RG58 is suppose to have a VF of 0.66 it does vary some from manufacturer to manufacturer. I havent bothered to work out how much difference it would make but would suspect that the longer the antenna (in elements) the worse it would become.

Am thinking of making a Sterba curtain for WiFi. Looks easier than playing with bits of coax!

Cheers Bob W5/VK2YQA East Texas

Almost exactly as much as there is between a coil that is a half
wavelength from a grounded surface.

Somewhat less then 2 amps. Loss certainly occurs along that length,
at that frequency? So what? Are you thinking that this is the
predominate mechanism that is altering the current magnitude through
your coil? It is part of the answer, but not the whole answer.

No current flows. Charges flow (move) the magnitude of that movement
past any point is current. I am picking nits, here, but the
distinction is important if you want to build on these simple
concepts. By the way, I am an EE, not a physicist, but I have to
think physics to do engineering.

> I guess I'm so dense that I need help in proving what you think

It wasn't derogatory, John. It was a paraphrasing of the old saying:
"When one is up to one's ass in alligators, it's hard to remember
that the original purpose was to drain the swamp."

> But if you get back to physics, I will soon lose interest in your mind.

I have no idea if "losing interest" is a good thing or a bad thing.

Odd you chose to deviate from technical discussion to explain
"seeming" in terms of fornication and masturbation. You offer no
quantifiables, and even more oddly, no qualifiables. Yours would be a
pretty strange reality.

I have answered with my opinion on that subject many times, already.
I am trying to help you build your understanding of it, so you can

argue it more persuasively, and understand it more completely. I'm doing it in public, to invite corrections from anyone who sees errors in my thinking, and can explain them to me.

If you have no interest in anything but butting heads with the people who have disagreed with you, then, please stop responding to my posts.

You have that choice.

Thanks to both of you for your help. I took the antenna down and by-passed the 40' of LMR 400. Still, my Rssi with the OEM antennas was only 3db better on the big antenna. Thinking maybe the radome was an issue, I took it off and saw about another 2db improvement.

I had fun building the antenna and I learned a lot. I just bought a pair of OEM high performance (9dbi gain) antennas off of eBay. Someone suggested running the router up my tower in an enclosure. Neat idea...

Hi Ken

You might want to look at an "Acess point" to locate up at the antenna so
you can still use the other ports in your router.

Jerry

Hey Dave, about the 'shielded, balanced line' idea --- you know how the whole idea behind using twinlead (or any balanced feedline, I guess) instead of coax is because twinlead (or any balanced line, i suppose) is supposed to much less lossy --- I'm wondering if I were to make a balanced line that is also shielded, like you suggested, would this not provide the best of both worlds? It would have the convenience of shielded coax (able to be run in places that twinlead couldn't) AND perhaps also be less lossy than coax? Or would it? How lossy would such a balanced, shielded feedline be? Do you know, offhand, Dave? I'm not well versed in RF circuitry. All I can really do is look at it in terms of it being a simple resistor, in which case, I suppose having 2 parallel feedlines would have half the ohmic losses (I think), but there's clearly a whole lot more to it than just this.
:)

Hi Ken

Further to my last about a narrow vertical beamwidth.

http://members.cox.net/vk2yqa/pattern2.png

Is a quick and rough modeling of a 16 el collinear. Note the half power beamwidth of only 4 degrees...

Cheers Bob

Does "somewhat" cover 24 dB of losses? :-) The point is that the
current "drops" by exactly the same amount as the voltage. That's
a characteristic of distributed networks as opposed to lumped
circuits. In a Z0 RF environment, the current has to "drop" by exactly
the same amount as the voltage to maintain the Z0 ratio. There are
really no "across" and "through" concepts as exist in DC circuitry.

Wow - that's sharp! It explains why I lost the signal in my front yard.

How about this version?

http://martybugs.net/wireless/collinear.cgi

I just built it out of a coat hanger, soldered to the old coax
feedpoint from the last "experiment". It performs pretty good
but I calculate 2.14db of losses in the line. Something my
back of the set antennas don't have to deal with.

What about expanding the above antenna?

Gamma Fans:

One area of practical interest for which Zo is not "real" occurs over
[broad] ranges is in the area of application of the so-called "last mile"
[for you Newbies that might be "first mile" (grin)] of POTS (Plain Old
Telephone Service) twisted pair transmission lines to a variety of
communications "last mile" communications systems.

Over the frequency ranges of interest for telephone cable applications i.e.
from below 25Hz or so for some signalling and on up to several hundred kHz
or even a few MHz for xDSL applications such as ISDN BA and HDSL, T1,
etc..., the telephone twisted pair exhibits a Zo that varies all over the
map!

In this arena, complex Zo and highly variable Gamma is the norm, in this
twisted pair media and for those kinds of applications, unfortunately for
Mr. Smith Zo is NOT purely resistive.

The Zo of twisted pair ranges rom very nearly purely capacitive impedance of
several thousand kOhms at low frequencies to purely resistive near 100 Ohms
at the higher ends.

Analysis and design of systems that operate over this 5-6 decade range of
frequencies must perforce use complex Zo!

Smith's venerable chart is completely useless. Smith's Chart is only for
"amateurs" who use transmission lines in very limited ways.

The complex reflection coeficient in all of its' glory reigns supreme for
those practical and realistic design and application scenarios.

Thoughts, comments?

Really good one Tom! Why twist and dance?
If you don't know what the impedance is please read 2005 ARRL Handbook: page
4.42 Impedance (re Inductance) and
page 22.1 Impedance (re Antennas)
If we measure current drop from one end of the the coil to the other, we see
current drop across the coil.
(You would love "through" because you can then "prove" that if it flows
through it has to be the same, right?)

> When you use "across", I guessed and thought you really meant "through"
> or "at each end".
>
> When you used "impedance", I couldn't guess and figure out if you meant

> It could mean too many things.

I meant freakantance, just could not express it :-)
Nice try! Keep on twisting. Before you didn't get it, now you don't want to get it.

Let's back off one more giant step back to measurements. Show where W9UCW was "cheating" in his test setup, pictures and comments at
http://www.k3bu.us/loadingcoils.htm
where he shows clearly that RF current drops significantly across (through) the loading coil, just like it drops across (through) the resonant antenna (piece of wire or tubing) from max at the base, to zero at the tip. I venture to say that (most) everybody knows that impedance of such resonant radiator is low, about few ohms, at the base to thousands of ohms at the tip. If you don't know or get that, no point of discussing current magnitude at the ends of the loading coil.

As a point of reference, commercial UHF broadcast TV transmit antennas can have elevation gains of 36X or more (~17.7 dBi); still they produce their predicted signal strengths for their ERP and height above ground over their line-of-sight coverage areas.

How are you, Peter? Is this some kind of religious controversy? I can't
imagine hams having any use for twisted pair transmission lines, but
maybe you can give your lines some fractal qualities, or show how
current can flow four directions at the same time in the same place in
them or the voltage at any given point on one of them must have 25
possible values simultaneously, or that the impedance on a typical line
is proportional to the square root of Cecil's forearm. In fact, giving
them any qualities that are impossible will endear them to
the great post hog on this newsgroup and start a never ending thread.

Cecil, W5DXP wrote:
"There is no phase information in standing wave current phase."

Kraus and Terman agree with Cecil.

Kraus writes on page 239 of his 1950 edition of "Antennas":
"It is generally assumed that current distribution of an infinitesimally thin antenna (l/a=infinity) is sinusoidal, and that the phase is constant over a 1/2-wavelength interval, changing abruptly by 180-degrees between intervals."

This agrees with Terman who writes on page 94 of his 1955 edition of "Electronic and Radio Engineering":
"When the load impedance does not equal the characteristic impedance (as at the open-circuit at the standing-wave antenna tip), the phase relations are complicated by the presence of the reflected wave. The phase of the resulting voltage (or current) then oscillates about the phase of the voltage (or current) of the incident wave , as illustrated in Fig. 4-5.The phase shift under these conditions tends to be concentrated in regions where the voltage (or current) goes through a minimum;----."

Pity the fool who argues with Kraus or Terman.

Best regards, Richard Harrison, KB5WZI

> of traveling oppositely traveling waves of different amplitudes?

Yes, but I wouldn't put it quite that way. I prefer to say that this is simply a special case of the more general result you get when you sum forward and reverse waves. Nothing magical or abrupt happens when the two traveling waves are equal in amplitude -- if they're slightly different, you get a little phase shift of the total current with position along the wire, the current minima aren't quite zero, and the spatial shape of the amplitude of the total current -- that is, the shape of the standing wave -- isn't quite sinusoidal. Making the amplitudes more and more different smoothly transitions the nature of the total current until in the special case of the reverse traveling wave being zero you have the distribution of a pure traveling wave.

Hi Ken

Note when I modeled the 16 element I did so as a series of dipoles fed in phase rather than use the coax/crossover design.

I felt like checking your statement about being unable to receive in the front yard. At around 45 degrees down from the antenna the NEC2 output says that you'll get a lobe between 20 and 30dB down from an isotropic (or 35-45dB down from the max gain) I'll admit my near close in signal theory doesnt really exist but a path of 800m has about 106dB of loss. If you knock that back to 12 metres (6dB every time you halve) you have about 70dB path loss. If you then take a WAP kind of power level of around 10dBm the RX signal at 12m with a halve wave is going to be around (10-70-25) -85dBm. This kind of corelates with the lowest usable signal for WiFi! There ya go!

I like the URL you sent as being more predictable/easier to construct that using bits of coax. Keep in mind that progressively longer and longer colinears are more and more critical to build and the construction method that is being used is not really optimal in the area of spacing between elements. You could probably pick a much better design. I think however that you need to sit back and consider what you are trying to achieve. Are you setting up a personal WiFi LAN for others to use or just for specific contacts? If you are wanting to work in one direction (or use a rotator) it might be more effective to use a corner reflector and maybe 4 elements in phase. This will be much less critical in construction. Remoting the WAP will make a lot of sense too as you'll lose the line loss! Comments?

Cheers Bob

This is a bit like the previous discussions on Buryflex!

I read an interesting article on the 'net by NEC on a production
system for foam dielectric coax for low microwave frequencies... it is
clearly a greater challenge than extruding PE for solid dielectric.

Reg's response is interesting, I draw the conclusion that a 'quick and
dirty' confirmation of quality of a foam cable is whether its measured
VF is close to spec, it is it off, so is the Zo likely to be off.

But most of the charts don't scale the area where the magnitude of the
reflection coefficient is greater than 1.

Point taken. They are tough to rotate, though. Also if you stack yagis
properly, things get much better.

That's great info, Bob - btw my router puts out +20dbm and the
background noise level in the receiver @ 2.422ghz is -97dbm +/-
2-3db....

As far as my purpose, I'm trying to get access when I go to a park
to go /p on 40m. I want to be able to access the DX cluster &
HF Pack users as well as check e-mail.

I did a little research and the antennas I bought on eBay are 7dbi
gain with, of course no feedline losses. No matter how much I
crunch the numbers, I just can't find a more cost effective system.

And, as I said, for some, perhaps many, contesting situations, low side lobes are a good idea. On the east and west coasts, it's often good to have as much F/B and F/S as possible because of the population density and direction of it, while in the midwest the situation is quite different, with few stations scattered all over the map, and it's desirable to have sidelobes and rear lobes around -15 or so.

I don't agree that this is a good test. The Z0 of cables with solid PE insulation varies considerably, and it's doubtful that the variation is due to variable dielectric constant of the solid insulation. So why should we assume that Z0 variation in foamed dielectric cable is due solely or mostly to the dielectric density?

That's right.

More important, didn't he say he is matching 35 ohm elements in a
vertical array. I'd think mutual coupling would cause much bigger
errors than the cable unless he is feeding the elements either at 0 or
180 degree phase. Why worry about Vf and cable impedance when the
lements are all over the place in impedance?
:-)

The thinking is more the case that the foam density / dielectric
constant is apparently very hard to control, and in cheap cables with
poor QA, a probably source of failure to meet spec.

Inductance core fans:

[snip]
> PS. interesting how pot cores have very little inductance change with
> changing gausse.
[snip]

Most, if not all, pot cores used for "precision" inductors and transformers come in matched pairs with a very accurately ground narrow air gap between the two center posts. The Al (or alpha from some mfgs) is accurately set by the width of the air gap as ground during manufacture. The air gap also forms a large part of the overall magnetic path (air having a much larger reluctance than the ferrite). Such pot cores for precision inductors usually have an adjustable slug (set with a non magnetic screwdriver) to allow the finally assembled inductor to be set to an "exact" value.

And so... pot cores intended for use in making precision inductors (as in filters or delay equalizers) or precision transformer applications exhibit little change in inductance over a wide range of conditions simply because of the air gap.

Displacement currents in the inductor and the very high reactance of
the very short antenna above the coil explain current difference.

Current cannot vanish Yuri. It has to have an alternative path.

I can change current difference at each end of the inductor all over
the place depending on the design of the loading coil, with NO change
in the loading coil position or antenna lengths.

It is the theory you have, that the current is tied to the "missing
degrees", that is wrong.

Without displacement currents there is no current difference at each
end of the coil, it is not caused by "missing degrees. It is caused by
the capacitance above the coil being very low and the capacitance of
the coil to the outside world being much larger. The current is not all
gone in the first few turns either. It is a series reactance/shunt
reactance problem.

Hi Ken

Well if you are going to a specific location (the park) you may as well use a directive antenna like a corner reflector/gridpack etc. In fact you could be real smart and use a 2m handheld and a low data rate link to swing the antenna in whatever direction you choose (eg packet talking to a home PC, PC connected to rotator. You could even make it as simple as a two state tone decoder for CW or CCW the antenna whilst watching the WiFi signal) There are some quite broad reflector based designs out there that give good gain on 2.4GHz. For example a 900x700mm gridpack will give you about 25dBi.

I guess you are using one of the amateur radio 2.4GHz channels? You can use a higher EIRP than the normal WiFi is limited to. (from memory 30dBm EIRP is the legal max for unlicensed use) You do need to identify though. (A simple text based ping might be enough)

I am surprised at the -97dBm sensitivity. The links I worked on in the past we used -87 for 11MB 802.11b predictions. I guess your figure would be at the lowest data rate and thus effective bandwidth. You can't beat Boltzmann! The Ethernet microwave data radios I work with nowadays need about 20-25dB s/n for a 50MB/sec channel that covers about 10MHz b/w. Thermal noise in 10MHz is about -103dBm so we need better than -83 for a good path. Our radios dont change speeds/bandwidth on the fly though. Interference will be your greatest enemy though...

One of you other posters suggested remoting the router box to remove the cable loss problem. It is the place where most of your problems lie. Even moving it part the distance will help. You might also look at a better coax. We use to use LMR400 extensively. It was much cheaper than RG213 and lower loss as well.

Oh and be careful with the WAP etc setup as regards "maximum distance". We had a problem early on where we left it at the default for a 10km path and the ACKs (or something) kept crashing and kept the speed down. The distance number introduces some kind of ACK delay..

Good luck!

Cheers Bob VK2YQA

There are two ways of modeling an inductor in EZNEC. One is by using an inductive "load". This is a pure lumped inductance, which takes up zero physical space and whose currents are equal at its two terminals. It does not couple or react at all to its surroundings other than via its terminals, and its voltage-current characteristics are dictated by that of a pure inductance, v = L di/dt. For a number of reasons discussed many times here, this isn't a good model for many or most typical loading coils.

The other way of modeling an inductor in EZNEC is by making it from conductors -- "wires" -- arranged in a polygonal helix. (EZNEC v. 4.0 provides an automated way to generate this structure.) These wires are treated exactly the same as all other wires in the model. As long as the turns aren't too close together (conservatively, closer than several wire diameters, but in practice good results are usually obtained with spacing as close as one diameter air space between wires), it does a very good job of calculating the inductor currents and radiation. (It's a little generous about loss if the turns are close because it doesn't account for proximity effect.)

EZNEC calculates the total current by first calculating the self and mutual impedances of every segment in the model from a fundamental equation, then using Ohm's law to find the total current in each segment from those impedances and the voltages from the user specified sources.(*) It's not aware of traveling or standing waves. The presence or absence of standing waves -- that is, a changing magnitude of current with position -- can be seen by viewing its output. Displacement current is a consequence of mutual coupling between segments -- in a dipole, the dominant coupling is to the other half of the dipole, and in a grounded monopole, to ground. However, each segment couples to every other, even on its own wire, and it's this coupling which brings about the current distribution that ultimately occurs.

EZNEC deals only with total currents and makes no effort to detect, use, or break up total current into individual traveling waves. It isn't aware of whether currents are "driven by traveling or standing waves" if for no other reason that no currents are ever "driven by" traveling or standing waves. Voltage differences cause currents which can be described as traveling waves. When multiple traveling waves are summed to find a total current, the amplitude of the sinusoidal current varies with position along the line, and this envelope is called a "standing wave". A standing wave is simply a description of the magnitude distribution of the total current along a wire or transmission line. It doesn't drive or cause anything -- it's a description of an effect, not a cause. All the fuss about standing waves is a diversion which confuses the issue and deflects attention from the salient issues involved in understanding the topic under discussion.

(*) This is a simplified explanation. For details, see Part I of the NEC-2 manual.

This is freakin unbelievable.
You think you are making fool of me and rest of us? You are not answering questions, nor engaging in the exchange. You keep pulling out crap, like first the current is equal, then
"" I can change current difference at each end of the inductor all over the place depending on the design of the loading coil, with NO change in the loading coil position or antenna lengths."

You are getting tangled in your own webs!!!
Tell us what is wrong with W9UCW setup and results. Where did he screw up, what is wrong, and show what you have measured in THE SAME type of setup. Not freakin W8JI coils, not at the base, no weird frequency, not twist and dance.
Just take 40m shorted vertical, make it resonant with DECENT coil like he has about 2/3 up the mast, stick the RF ammeters at both ends and give us the readings. You have the pictures, you should be able to replicate the setup.
Then you tell us that the current is the same at both ends, show us the pictures and describe your setup, meters, frequency and results.
This goes for the rest of the "gurus" that insist on the same.
Then model the loading coil as a solenoid or loading stub of same inductance in EZNEC and show us what you get. Cecil did it, and the silence is deafening!!! Can you explain what is "wrong" with Cecil's examples?

Looks like Belrose should get another pHDuuhh for starting all this misconception and misinformation in ham literature. Pathetic is that some of the "gurus" that should know better, are on the same bandwagon to la-la land.
Stop crap and twist and dance, answer the freakin questions or say nothing. We are not idiots that you BS with "you don't know what I mean by impedance".
So what happened to impedance? Now you know what it is, or is pink electron displacement capacitance current phasor phase mumbo jumbo?

PRICELESS!!!!!
So WHAT IS THE CURRENT AT THE TOP OF THE RESONANT 90 deg (any) VERTICAL?
Same as at the base, because "Current can not vanish Yuri"?
You are jerking our chain or have a real problem.

Suggestion: do some reading on impedance, resonance, standing waves, current and voltage distribution along the antennas, and look at the current curves in books and as produced by EZNEC. Looks like you have no clue how antennas work.

You can have another "last word" that will "show" that you "know" what you are talking about.

It's been quite a few years now, so things might have changed. But some time back I learned a bit about the ferrite manufacturing process. It turns out that the green ceramic shrinks by something like 20 or 25 percent during the firing process, with poor control over the amount of shrinkage. The gaps in gapped pot cores, I found, were only nominally the specified gap width -- each pot core was individually ground to meet the Al specification, not some specification on air gap size. This isn't important in using them, but I found it interesting.

What you get with an air gap in trade for effective permeability, is much greater independence of Al from the core characteristics (material permeability and physical size) and therefore much greater stability with regard to temperature and flux density, and much greater flux density capability.

The antenna was a trussed whip for 10-30 MHz. The truss frame was
stabilized by four turnbuckles connected to the base through ceramic
insulators. One of the RM's had bonded across the insulators. We were
about to do a routine megger check when my partner spotted it. We couldn't
believe our eyes.

EMI bond straps are appropriate for a lot of things topside. That wasn't
one of them. :-)

Forward current is one amp at zero degrees. Reflected current
is one amp at 180 degrees. That creates a standing wave
current node where net current is zero. It has "vanished"
due to superposition.

> or break up total current into individual traveling waves.

Then, without effort, EZNEC accurately reports the presence
of traveling waves or standing waves as can be seen from
the graph of the EZNEC results at:

http://www.qsl.net/w5dxp/travstnd.GIF

The graph on the left is for traveling wave current. Its
magnitude is fixed and its phase varies with wire length.
Traveling wave phase can be used to determine the phase
shift through the wire (or through a coil).

The graph on the right is for standing wave current. Its
phase is fixed and its magnitude varies with wire length.
Standing wave magnitude can be used to determine the phase
shift through the wire (or through a coil) by taking the
arc-cosine of the magnitude.

Here's a partial answer:

I had a 2M copper pipe j-pole suspended vertically and well away from any other metal. I ran the coax through a switchable attenuator into a radio tuned to a local repeater with fairly steady chatter. I set the attenuator to put the radio deep into the noise -- a few dB away from Gone. Then , I took a length of mast, held it vertical and slowly approached the j-pole. I had to get within about one inch to affect the chatter. The direction from which I approached didn't seem to matter. Next, I did a similar experiment on transmit while watching reflected power and saw essentially the same effect.

Theoretically, I think the added capacitance simply detunes the radiating element when a mast is really close, meaning an inch or less. Otherwise, the mast isn't seen as director, since the size is so far off. (Guessing is allowed, right?)

What is it you are after?

I already posted, years ago, measurements at:

http://www.w8ji.com/mobile_antenna_current_measurements_at_w8ji.htm

> Then you tell us that the current is the same at both ends, show us the
> pictures and describe your setup, meters, frequency and results.

I think what is happening here is you are getting angry and not paying attention to what people are saying. I've already said it is possible to have different currents at each end of a loading coil.

What I disagree with you about is you seem to attribute that difference to some magical property related to the distribution of current based on electrical degrees the loading coil replaces or standing waves, and that is very simply and clearly wrong.

Current cannot "drop" or be "dropped". It can be divided between paths, but it cannot vanish into thin air. The mechanism that allows current to change in an antenna is displacement current, and it comes from capacitance.

The only thing wrong with Barry's setup is he uses large meters compared to the size of the coil, and they are invasive. The meter requires cutting the leads and adding a fairly large bulk into the system. I'd never use thermocoupler meters to measure high impedance systems, magnetic-field coupling systems can be smaller, have less distributed capacitance, and don't require rerouting leads. Current transformer systems are also more accurate and can have much better resolution, and can even be used to determine phase.

Let's not let the measurement method overshadow the real disagreement, however.

The real disagreement is you seem to be saying the missing area of antenna replaced by the inductor and standing wave patterns of current distribution in the antenna are what causes the loading coil to behave as it does. Barry also proposed that, if I am not mistaken.

That is not true.

The single thing that allows an inductor to have a current difference
and phase shift in current along the coil or at each terminal is the
capacitance of the coil to the outside world. That is why we would have
to be very careful NOT to disturb the coil by mounting other large
measurement devices on the coil.

> This goes for the rest of the "gurus" that insist on the same.

The "gurus" you despise go back to Maxwell, who described displacement
current:

http://maxwell.byu.edu/~spencerr/websumm122/node72.html

The term displacement current is not an invention of those you call
"gurus". It is part of physics dating way back to the 19th century.
THAT is why so many people are trying to tell you about displacement
currents, it isn't to make you feel bad.

You have to include displacement currents in any model, or you cannot
have a current taper along the length of a conductor.

> Then model the loading coil as a solenoid or loading stub of same inductance
> in EZNEC and show us what you get. Cecil did it, and the silence is
> deafening!!! Can you explain what is "wrong" with Cecil's examples?

Sure. His explanation of what is happening and the fact he picked a
very special conditions just to satisfy a twisted theory. Roy showed in
his models why Cecil's conclusions were wrong. Practical measurements
will show the same thing.

The ONLY thing that allows a conductor to have current taper along its
length is displacment current. That is a function of the capacitance
from that conductor to the world around that conductor compared to the
impedance presented by the system beyond that point. It is NOT
determined by standing waves. It is not determined by "missing length
replaxed by coil".

> Looks like Belrose should get another pHDuuhh for starting all this
> misconception and misinformation in ham literature. Pathetic is that some of
> the "gurus" that should know better, are on the same bandwagon to la-la
> land.

I'm not sure what motivates you to attack everyone, but at least you
universally seem to hate almost everyone. Jack Belrose is a great guy
and has contributed a great deal with his work. If you finmd something
wrong with what he is saying, tell us what it is. Don't attack the
person, point out the error.

> Stop crap and twist and dance, answer the freakin questions or say nothing.
> We are not idiots

I suppose everyone has a right to their own opinions on that topic.
I've done my best to answer the questions. I hope this post helps
clarify things. Calm down, there is no need to get upset.

Did this help answer your questions?

Harbin wrote:
> Counterpoise wire length. I've heard that it should be 1/4 wave, and then again I've
> heard it should be 1/2. Which is correct, or will they both work?

The lowest impedance presented by a single counterpoise wire is when
the counterpoise is resonant and 1/4 wl long electrically.

When a single counterpoise wire is near 1/2 wl long and resonant, it
has a very high end impedance.

If the counterpoise is under a dipole or some other antenna just to
isolate it from ground losses, a 1/2 wl long counterpoise or longer is
best.

If the counterpoise is used as a termination to allow forceing current
into a Marconi antenna or an end-fed antenna, or used to provide a
ground path for unwanted currents, it is best if it is 1/4 wl long.

More counterpoise wires are always better, because the more you use the
less critical length is and the lower loss is. There is of course a
point where more won't help. With 1/4 wl wires, 50 or so placed
radially are near perfect. Adding more won't make a noticeable
difference. Once the counterpoise wires are .025 to .05 wavelengths
apart at the widest points, adding more will generally not help.

I use 100 200 foot long wires on one of my 160 meter verticals. On my
other verticals I have 1/4 wl radials, and once I reached 40-50 radials
adding more made no measureable difference at all.

Jack Belrose, VE2CV, is a highly respected engineer and scientist with an extensive and distinguished professional history. We're very fortunate that he's shared some small part of his extensive knowledge and experience with the amateur community. For a glimpse at his career, see http://www.friendsofcrc.ca/Articles/Belrose-EarlyYears/Belrose%20remembrances.html. No one is always right, but people like Jack have earned my respect and I'll always listen very carefully to what they have to say. Although it doesn't bear directly on his credibility, I've known him for many years and I heartily agree with Tom that he's a great guy.

Those are RMS standing wave measurements. To see what is wrong
with using RMS standing wave measurements please see:

http://www.qsl.net/w5dxp/travstnd.GIF

> I think what is happening here is you are getting angry and not paying
> attention to what people are saying. I've already said it is possible

And there phase information in those standing wave current
magnitudes. There is no phase information is standing wave
current phase.

> What I disagree with you about is you seem to attribute that difference
> to some magical property related to the distribution of current based
> on electrical degrees the loading coil replaces or standing waves, and
> that is very simply and clearly wrong.

No, it is your misconceptions about standing wave current
that are very simply and clearly wrong.

> Current cannot "drop" or be "dropped".

RF current drops with the attenuation factor, just like RF
voltage does. Clinging to the lumped circuit model
presuppositions is what causes you to make silly assertions
like the above. Standing wave current periodically drops
to zero in unterminated transmission lines.

> The single thing that allows an inductor to have a current difference
> and phase shift in current along the coil or at each terminal is the
> capacitance of the coil to the outside world.

Is capacitance to the outside world also what allows a wire
to have zero current at one point and two amps of current
90 degrees away. Of course not! The degrees of delay through
the coil is primarily responsible for the difference in
current. That, and where it is places on the standing wave
current curve.

> You have to include displacement currents in any model, or you cannot
> have a current taper along the length of a conductor.

We are talking about displacement current to earth ground and
there is zero displacement current to the outside world ground
yet there's SWR current taper on coaxial transmission lines.
Maybe it's time for you to learn how to add phasors?

> Sure. His explanation of what is happening and the fact he picked a
> very special conditions just to satisfy a twisted theory. Roy showed in
> his models why Cecil's conclusions were wrong. Practical measurements
> will show the same thing.

Roy used standing wave current phase to try to measure the
delay through a coil. That's an invalid measurement. None of
my conditions are special. They just seem special to your
lumped circuit model. The distributed network model works
for all conditions.

Tom, W8JI wrote:
"The ONLY thing that allows a conductor to have current taper along its length is displacement current."

In a-c circuits, added to ordinary conduction current there is displacement current, at right angles to the direction of propagation, determined by the rate at which the field energy changes.

Also at right angles to the direction of propagation, and determined by the rate at which energy changes, there is a changing magnetic field, in addition to the changing electric field. Together the electric and magnetic fields exchange energy and produce radiation.

Displacement current which is the a-c current through a capacitor, that has no d-c conduction, is not the"ONLY" thing that allows a conductor to have a current taper along its length.. A conductor can lose energy through dissipation and radiation forever, not just relocate it temporarily through storage in a reactance.

The dissipation line at the end of a rhombic antenna does not handle the entire output of the transmitter at its other end. Most of the energy is already radiated by the time it reaches the dissipation line.

Best regards, Richard Harrison, KB5WZI

Cecil,

Sorry, you cannot pick and choose which displacement currents to consider.

It might be helpful to go back to review the fundamentals of Maxwell's equations, including the continuity equation for current, before making these inane comments.

Richard,

That is incorrect, and even Terman never said such a thing.

Charge is not created or destroyed. It either keeps moving as current, or it is stored. Charge storage is the equivalent of displacement current. The terminology is slightly confusing at times, but it has not changed for over 100 years.

Detailed discussions of this topic are found in virtually every intermediate and advanced textbook on electricity and magnetism.

Somebody finally got the problem.

Side lobes smaller than -20 dB are better. Smaller than -20 dB is -25
dB, -30 dB.

If it was stated as "-20 dB or less", that could/migh be interpreted as -15
dB, -10db. It is a language problem.

Now... What was the OP really asking? and what was the author really trying
to say? Probably what most assumed, but that isn't what he wrote.

Speaking as a lurker, I find Roy's and Tom's postings very educational and I appreciate the time they take to do it.

I am a little dense, but I think I have learned four key points (at least, key for me) from this material:

1. One can discuss transmission lines and antennas using pulse analysis or steady-state analysis. When these two are mixed together the results can be a mess.

2. When discussing "phase difference" we need to specify the two components that have the difference. (I.e., phase difference between the current into and out of an inductor is a different animal than the phase difference between current and voltage at a specific point.)

3. Superposition ("adding together") of power computations is not valid in reactive circuits.

4. Displacement current is as real as any other current when dealing with antennas and their components. (I cannot remember "displacement current" ever being mentioned back in the dark ages when I was in EE school. Perhaps the school should remain nameless.)

Hello,

Does this seem logical?

1. The signal strength (example in dBm or mW) from a transmitting source is measured.
2. Assuming most of the attenuation is due to free space loss, the free space loss factor is "added" back to the measured signal to get the ERP of that specific radiation lobe (it could be main, side, or back lobe).
3. The transmitter output is a known value (example 2 Watts).
4. Using the calculated ERP for a specific lobe, I can use the following to determine the loss / gain due to the antenna & cable: loss/gain = 10 log (transmitter output / ERP specific lobe).
5. If I rotate the transmitting antenna to 360 degrees, then I should be able to have a rough picture of its azimuthal radiation pattern at a certain elevation angle.

I'm probably using the terms the wrong way because I think ERP is synonymous to the main lobe of the antenna (right?). But I'm just treating the ERP as specified only to a certain lobe without knowing if its the main, side, or back lobe.

I'm really not sure if this is right. I just want a confirmation whether my logic is wrong, and if so, why? Thanks!

I think you make the issue too complex.

ERP = P[antenna]*[antenna Gain]

Example ERP = 400 Watts = [100 watts power]*[Gain of 4]; or,

ERP = 50 dBm + 6 dB(antenna) = 56 dBm = 400 watts.

Energy in the side lobe is then 56 dBm +[sidelobe in dB(antenna)].
Where the side lobe could be -20 dB yielding 36 dBm ERP in the side lobe.

All you need is a line where R/L=G/C. This is the famous distortionless
line. It was probably invented long before Chipman. I don't know what
an amateur would want one for.

> a mess.

True. You can actually translate from one to the other, but it requires an FFT or its inverse. Attempts to mix the two nearly always leads to invalid conclusions.

> 2. When discussing "phase difference" we need to specify the two components
> that have the difference. (I.e., phase difference between the current into
> and out of an inductor is a different animal than the phase difference
> between current and voltage at a specific point.)

Yes, although we can use an arbitrary reference as long as it's the same for all components. For example, if one current has a phase angle of 50 degrees relative to some arbitrary reference and the other has a phase angle of 30 degrees relative to that same reference, we know that the phase of the first relative to the second is 20 degrees.

> 3. Superposition ("adding together") of power computations is not valid in
> reactive circuits.

It's never valid. Let me give you an example. Consider two AC or DC voltage sources, each of 10 volts amplitude, with their negative terminals connected together. (If they're AC, have them be of the same frequency and in phase.) Connect a 10 ohm resistor between their positive terminals. Superposition says that we can analyze the circuit with each source individually and the other one turned off (short circuited in the case of a voltage source), and add the results. What we get should be the same answer as a full analysis with both the sources on at the same time. So let's do it. Turn off source #2. The current from source #1 through the resistor is 1 amp. The voltage across the resistor is 10 volts. Now turn source #1 off and #2 on. The current through the resistor is 1 amp going the other way than before, or -1 amp. The voltage across the resistor is 10 volts, but in the opposite direction as before, or -10 volts. Adding the results gives a total of 0 amps through and 0 volts across the resistor. That's the right answer --

it's what we have when both sources are on. But now look at the power dissipated by the resistor. With only source #1 on, it's I^2 * R = 1^2 * 10 = 10 watts. With only source #2 on, it's (-1)^2 * 10 = 10 watts. The sum of the two is 20 watts, which is not the dissipation with both sources on. Superposition does not apply to power, period. If it ever seems to, it's only because of coincidence.

Don't be confused by the "forward" and "reverse" power concept. This is not superposition and the concept must be used with great care to avoid reaching invalid conclusions.

> 4. Displacement current is as real as any other current when dealing with
> antennas and their components. (I cannot remember "displacement current"
> ever being mentioned back in the dark ages when I was in EE school. Perhaps
> the school should remain nameless.)

It's a useful concept, but also has to be used with care because it isn't a real current consisting of movement of electrons. Current in one conductor creates a field which induces current in another conductor, making the current appear to have "flowed" from one conductor to the other. The classic example is of course current flow "through" a capacitor. "Displacement current" is a widely used term; it's in the index of the first four EM texts I grabbed from the bookshelf. Of an example of a parallel RC circuit in Kraus' _Electromagnetics_, he says, "The current through the resistor is a *conduction current*, while the current 'through' the capacitor may be called a *displacement current*. Although the current does not flow through the capacitor, the external effect is as though it did, since as much current flows out of one plate as flows into the opposite one."

Displacement current appears in Ampere's law, one of the four Maxwell equations. In one formulation it has the quantity i + d(phi)e/dt on one side. The i is conduction current, and the derivative quantity is known as the displacement current.

Hello:

Just started to string up the new listening only antenna I purchased from PAR.

As there is a Balun between the start of the wire antenna, and the coax feeding the receiver, a ground bar is apparently required.

Am using the typical eight foot long,5/8" diameter Cu plated steel that I guess is fairly typical for house AC power grounding.

Querstion: At my age, it's a bit of a problem pounding in the six or seven feet that is commonly mentioned as the "required" length. Certainly, the more the better, I guess, but what wqould be a reasonable length into the ground ?
How about 4 to 5 feet ? Again, it's for receiving only.

Thanks,
Bob

Not everyone is happy with the term "displacement current." Albert Shadowitz, in his book _The Electromagnetic Field_, has a chapter entitled "The So-called Displacement Current." The term isn't in the index to Feynman's _Lectures on Physics_. (At least I couldn't find it.) All that is academic to the fact that AC current seems to be able to make its way through a capacitor with no more opposition than the capacitive reactance. Fortunately, no one on this newsgroup has any objection to the way the term is commonly used.

Check my article that describes the controversy, shows some proof of reality
and then efforts of the "gurus" to deny it and "reason" why it can't be so.
http://www.k3bu.us/loadingcoils.htm
The problem is that back in 1953 in QST article there was erroneous
conclusion/statement made, which propagated through the books, until W9UCW
measured the current across the loading coils and found that there is
significant drop from one end to the other, and the rest is (ongoing)
history

Thomas,

I'd suggest a remote tuner. You can have twinlead directly to the tuner, and then your entire run of coax sees a nice flat 50 ohms.

A nice automatic tuner would be ideal; you don't have to worry about controls. The price is not exactly right, since you've already got a tuner...

If you've got a well stocked junk box (op amps, power transistors, maybe a few multiturn pots) you could try my approach. I put a small gear motor and sensing potentiometer on each shaft of my MFJ tuner, stripped the spring detent balls out of the inductor switch, added a servo circuit (very simple, it's an op-amp and a couple of transistors) and can use the tuner more or less as if it were in the shack.

See http://www.n3ox.net/projects/servo for more information if you're interested. Your MFJ-949 would lend itself nicely to this approach. It can be done on the cheap, maybe.

A problem arises if you don't have 10-turn (or at least 360 degree) pots... I've been thinking about this in that they're sort of the weak point of my tuner project, as they're something like $15 per new. I work in a physics lab and every few months an obsolete homebrew instrument with a load of them hits the dumpster, so I'm set.

I think remote tuner of some description would be superior from a loss standpoint to any feedline tricks you could do.

Now, the balanced, shielded line on the concrete is a good idea if you're set on running twinlead all the way back to the shack. This is quicker and easier than than building a remote control for your tuner, and cheaper than buying an autotuner, so you might try it first and see if you're happy with the results.

In my apartment, I originally ran about 20 feet of 75 ohm coax between the antenna feedpoint and the tuner. I made some contacts, but saw a DRAMATIC difference when I put the tuner at the antenna feedpoint instead. Fewer RF feedback problems too.

Twinlead is better but twinlead isn't magic. Wide spaced open wire line with an insulator every couple of feet only is super low loss even with high SWR. 300 ohm twinlead, AFAIK, isn't.

> already radiated by the time it reaches the dissipation line.

For instance, consider 100 ft. of 50 ohm coax with losses of
3 dB driving a 50 ohm load from a source of 200 watts.

At the source, we have 100 volts at 2 amps. At the load, we
have 70.7 volts at 1.414 amps. The current dropped by exactly
the same amount as the voltage. Hint: The V/I ratio must be
maintained at 50 ohms for flat lines.

Anyone who doesn't understand RF H-field (current) drop in
a lossy transmission line has probably been so seduced by his
lumped circuit model that he thinks the model dictates reality
instead of vice versa.

Myron,

I built a set of tuned rings to couple a 4MHz signal from an ultrasound transducer to its processing/signal generation box. I used a small copper ring (only about 6") split at one point with a resonating capacitor across the gap on the ultrasound box side. The coax was connected across this gap also.

On the transducer side, use an identical loop and capacitor but make a series resonant circuit (capacitor in series with one of the feedline leads). Loops were separated by about 1/4 inch.

I know this configuration (parallel resonant on the transciever side, series resonant on the "antenna" side) worked the best.

It worked well in terms of passing the signal through undistorted (looked at amplitude and phase on both sides of the circuit, only got a bit of a phase shift, no amplitude loss)

I don't know about power handling. If you use hefty capacitors, there should be no problem. Bandwidth could be quite low with high-Q circuits, but maybe you could use variable caps.

I think your idea with capacitative coupling with inductors to tune out the reactance would work fine too, but I haven't tried that.

Anyway, the inductive thing works OK. I got the idea from a older (1950's?) ARRL antenna book that touted it as a way to allow rotation a parallel-line fed beam.

You'd certainly need a set of coupling rings for each band of interest, or switched or variable capacitors.

Low E glass would get some eddy currents going. I don't know how conductive it really is though, so ... who knows?

Why not? All I (and probably Yuri) have ever been considering
are displacement currents to earth ground from the coil. That
is the only current flowing sideways from the coil to ground.

That's interesting. It prompted me to look at my other electromagnetics texts. Of the eight I have (Johnk, Jordan & Balmain, Kraus, Ida, Majid, Holt, Ramo et al, and King), all include displacement current in the index and all discuss the concept. Only King objects to its use, although he notes that "The second term [in Ampere's law] was called the 'displacement current' by Maxwell, and this name continues to be used." He goes on to say that "Actually this terminology is unfortunate because the word displacement belongs to the old ether model and because the word current means specifically moving charge." He adds further reasons for his objection in the following paragraphs. With a copyright date of 1945, King's book (_Electromagnetic Engineering_, Vol. I) is the oldest of the texts I have. Perhaps the term has become more acceptable as time has passed. I do see why physicists such as Feynman wouldn't be accepting of the term.

As I mentioned in my earlier posting, it does need to be used with care. We have to always keep in mind that it isn't a real current and therefore doesn't always behave like one. But it is a useful concept as long as we stay aware of its limitations.

If you do try that, I recommend keeping the Q as low as possible. Otherwise, voltages will get very high, and you might well end up with greater loss as well as other problems. Minimizing the Q means keeping reactance values low which in turn means making C as large as possible. This leaves you with less reactance to compensate for. In other words, don't make the C small and try to compensate for the large amount of resulting reactance.

> original discussion about anyhow?

As I realized what the actual misconception really is, the discussion
shifted from coils to standing waves. Seems to me, W8JI and W7EL do
not understand the difference implied by these two different equations
(assuming |Ifor|=|Iref|).

Ifor = I1*cos(kx+wt) and Iref = I1*cos(kx-wt)

Istnd = I1*cos(kx+wt) + I1*cos(kx-wt) = I2*cos(kx)*cos(wt)

Gene Fuller has kindly explained the difference but W8JI and W7EL
seemed to have ignored his explanation. Gene says there is no
phase information in standing wave current phase and I agree.

> As in Cecil says what, and those disagreeing with him say what?

Looking at: http://www.qsl.net/w5dxp/travstnd.GIF

I say the RMS standing wave current's unchanging phase on the right
hand graph, cannot be used to measure phase. W7EL continues to report
those phase measurements as valid indicators of delay through coils
when installed in standing wave environments. I say all the phase
information in the standing wave current is in its magnitude which
is a cosine function as explained in Kraus and Terman. W8JI and W7EL
both dismiss the phase information in the standing wave magnitude
and insteadtrust the standing wave phase to yield valid delay
measurements.

> I'm curious how something that doesn't seem that complex can
> generate so many weeks of acrimony and vitriol! I don't know the answer
> - but then again, I'm not really sure what the question is. But I do
> know where to look it up....

Now you know what the argument is about. Seems to me, W8JI, W7EL,
and others possess misconceptions caused by assuming the unproven
presuppositions of their lumped circuit model. They "prove" their
misconceptions by making measurements known to be invalid. I can't
tell if they are aware of what they are doing or not.

If you know where to look for the answer, please tell us. I have
looked and only found a clear explaination in "Optics" by Hecht.

A side argument is whether standing wave current can drop to
zero at a node in an unterminated transmission line. W8JI continues
to assert that current cannot drop without some imagined third path.

Here's an associated quote from "Electromagnetic Engineering"
by R.W.P King: "an adequate representation of the reactance
of a coil with a nonuniformly distributed current is NOT
POSSIBLE in terms of a coil with a uniform current [a lumped-
element inductance] connected in parallel with a lumped
capacitance."

Gene Fuller wrote:
"This is incorrect, and even Terman never said such a thing."

I had written:
"Displacement current which is the a-c current through a capacitor, that has no a-c conduction, is not the "ONLY" thing that allows a conductor to have a current taper." It was Tom, W8JI who shouted: "The ONLY thing etc." I just said displacement current is NOT the only thing. Energy level often declines between ends of a wire or coil due to losses from radiation or dissipation in the wire or coil. Tom is mistaken.

I don`t find the subject of "displacement current" listed in my Terman`s index. I think its definition is accepted. but I gave mine in case someone did not understand what it is.

J.C. Maxwell unlocked the secret of radiation when he speculated displacement current would produce magnetic lines of force the same as conduction current does, thus a traveling E-field produces an H-field and vice versa. It`s been proved correct.

Terman writes on page 1 of his 1955 edition:
"Electrical energy that has escaped into free space exists in the form of electromagnetic waves. These waves, which are commonly called radio waves, travel with the velocity of light and consist of magnetic and electric fields that are at right angles to each other and at right angles to the direction of travel."

Terman writes on page 866 of his 1955 edition in his chapter on "Antennas":
"A wire antenna is a circuit with distributed constants; hence the current distribution on a wire antenna that results from application of a localized voltage follows the principles discussed in Chapt. 4, (titled"Transmission Lines") and depends upon the antenna length; mesured in wavelengths; the terminations at the ends of the antenna wire; and the losses in the system."

Nothing I wrote conflicts with Terman. That`s not the kind of fool I am.

Best regards, Richard Harrison, KB5WZI

Yuri,

I know you aren't going to like to hear this, but your article incorrectly claims the current difference (you call it current drop) is related to the electrical degrees the coil replaces.
That is not accurate.

ON4UN's book was initially incorrect.

Consider a short vertical antenna. If the current is uniform through toploading, radiation resistance is higher and current lower throughout the radiator.

If it is base loaded, current becomes nearly triangular in distribution. Current into the vertical actually doubles so we have the same number of ampere-feet. It always requires the same number of ampere feet to radiate the same power as EM radiation.

The job of the inductor in either system is simply power factor correction, to bring voltage and current into phase. We have a large voltage drop across the coil, but current does not change. phase shift and delay of current through the inductor will also be very small, zero in a perfect coil.

That is in an ideal antenna with very small stray capacitance to the outside world compared to the antenna area above the coil.

If we have a physically large coil, the coil MIGHT have significant capacitance compared to the antenna area above the coil. In this case there would be a difference in current between the bottom and top terminal of the coil, and there would be phase difference in the current entering and leaving the coil, but it is a result of current being shunted off through displacement currents.

The exact amount would depend on the physical size of the coil and the capacitance compared to the antenna above the coil.

There is not any magic to any of this, and we don't need to have standing waves. It is incorrect to consider the coil behavior and antenna currents by making the coil "act like" it has the missing electrical dgrees or replaces a section current curve in the antenna.

I can have one antenna and use a good coil design that has essentially no current difference at each terminal, and replace it with a very large (or poorly designed) diameter coil that has large differences in current at each end. Probably the ultimate in poor coil design for base loading is a linear loading system or stub, while the best would be a compact coil with nearly equal diameter to length.

The very fact we can change distribution all over the place with only a change in loading inductor design proves your theory incorrect.

Please try to not extract certain sentences from long explainations to distort the overall picture of what really happens, and of what I am describing.

The fact is, we cannot model or predict the behavior of a loading system without knowing the displacement currents. Neither wave theory nor "missing antenna length" theory will paint the correct picture of what is going on, and neither will give an accurate answer to a wide variety of real world systems.

By the way, this did not start with Belrose and it is not a QST or Handbook problem. The Antenna Engineering Handbook by Jasik and dozens of other college or engineering textbooks all deal with the problems the same way. If you are looking to libel anyone, you need to go all the way back to James C. Maxwell in the 19th century. It was before the Civil War that the "big error" you and Barry found started.

I guess it all comes down to if Barry and Yuri are right, or if nearly every professor, scientist, and engineer from Maxwell to today are correct. I can measure ANY antenna and prove things behave as I described. Can you do the same?

On the contrary, you must not have read W7EL's recent posting where
he again presented his coil delay "measurements" using the standing
current phase as a measurement reference. Remember, the current you
said contains no phase information? Maybe you should share your
knowledge with W7EL?

When you made your posting, you reinforced my argument better
than any other reference. I am very happy with your posting
and cannot thank you enough. I will continue to use it as
one of my best references for the invalidity of W7EL's coil
delay measurements.

The current drop in a wire with standing waves is indeed related
to the number of degrees occupied by the wire. Why shouldn't the
same thing be true for a coil?

> Consider a short vertical antenna.

Consider a 1/4WL vertical antenna. The current drop is a function
of the cosine of the number of degrees one moves away from the
source. The same thing is true for a helical antenna. The same
thing is true for a half helical - half wire antenna.

> I guess it all comes down to if Barry and Yuri are right, or if nearly

1. You assume the unproven presuppositions of your lumped circuit
model with a religious-like fervor.

2. You make invalid measurements using standing wave current whose
phase contains no phase information. All the phase information is
known to be in the magnitude measurement, but you dismiss any of
the proven arc-cosine calculations as bogus.

With misconceptions and invalid measurements, it is no wonder that
you can prove anything in the world even when it violates the laws
of physics.

Would you rather discuss something for which no disagreement
exists, or discuss the real point of disagreement?

It is apparent to me that the problem is not with coils. The
same point of disagreement exists whether a coil is present
or not. That point of disagreement involves standing waves,
not coils. Take away the coil and the misconception still
exists when discussing only a straight wire.

W8JI is still maintaining that the current cannot drop to
zero at a standing wave current node when the forward
current and reflected current are of the same magnitude.

That is obviously the point of misconception and it has
been clear ever since he refused to discuss zero amps
at the bottom of the coil and 2 amps at the top of the
coil. Replace the coil with a straight wire and W8JI
still has that same misconception. So you see the coil
is not the source of the disagreement.

Hi Richard,

My point is in complete agreement with Tom, W8JI. The only thing that allows "current taper" is displacement current.

Conservation of charge is one of the most fundamental laws in nature. The historical basis for referring to storage of charge in a capacitor as "displacement current" is considered incorrect today. However, the underlying physical science remains intact. "Current taper" means that charge stops moving as current and becomes stored in a capacitor. (Everything has capacitance; there is no requirement for a little lump with two leads on it.) It is this charge storage phenomenon that is known as displacement current.

Energy levels and losses have nothing to do with this question.

Cecil,

Your own calculations would appear to support Tom's assertion.

I believe after a long series of EZNEC models and RRAA messages you came to the conclusion that the 75 meter bugcatcher coil at 4 MHz had a traveling wave phase shift of around 10 degrees. I won't get into the discussion about whether this has any bearing on a standing wave antenna; let's just assume it does.

This same coil resonated an antenna with a whip length of 10 feet or so. A quarter wavelength at 4 MHz is around 60 feet. The phase shift that could be attributed to the whip is therefore around 15 degrees. The phase shift of the missing 50 feet of wire for a plain quarter wave antenna would be around 75 degrees.

Is 10 degrees the same amount as 75 degrees? Is this problem stated incorrectly? Why is Tom wrong?

Hi Tom, and others,

The "labeled" currents span a much too small arena. There are also
the induced currents (no, not necessarily from flux linkage) and
convection currents (which IS the primary correlative to the induced
current).

The convection currents are possibly the only current that attain the
speed of light velocity. The others are so astronomically slow, that
it is arguable to say that any current (electron/hole transport) in a
wire is any more significant than that that is supposed to never cross
through the dielectric of a capacitor.

In other words, the displacement current is labeled fictitious because
no electron ever moves from one plate to the other. Now, if we simply
substitute solid gold for that dielectric (still maintaining the same
plates); then no electron ever makes it from one plate to the other -
and yet current flows in the entire AC circuit by proportion to the
impedance presented to it by either the dielectric capacitor, or the
gold capacitor.

This, of course, illustrates the corruption of usage in the term
"current."

Gene Fuller wrote:
> My point is in complete agreement with Tom, W8JI. The only thing that
> allows "current taper" is displacement current.

True, but it doesn't happen as W8JI describes.

The distributed capacitance in a coil causes a transmission
line effect. The displacement currents cause delays (phase
shifts) in traveling wave currents. The traveling wave
currents can be considered to have constant magnitude, i.e.
negligible current taper in the traveling wave in spite
of the known displacement currents.

The displacement current effect on traveling waves is in
the phase, not the magnitude. Such is illustrated as an
EZNEC result in the left hand graphic at:

http://www.qsl.net/w5dxp/travstnd.GIF

Please note that in spite of the distributed capacitance,
the magnitude is fixed and flat, i.e. no taper. The displacement
currents cause phase shift delays in traveling waves but has
virtually no effect on the magnitude of the traveling wave.

The distributed capacitance is the same in the transmission
line whether a single traveling wave is present or standing
waves present. So displacement currents don't necessarily
result in current taper. How do you explain that one?

Now take a look at the right hand graph involving standing
wave current. The *phase is fixed and unchanging*. The magnitude
of the standing wave current is *tapered as a cosine function
of distance from the source*. Displacement current indeed does
cause this effect but it is a transmission line effect of
superposition of forward and reflected waves, not the effect
of some imagined sideways third path for current to earth ground.

Sorry Richard, that is not correct.

Radiation does not cause current taper. Dissipation does not either.

Consider dissipation first. If dissipation caused current reduction,
the return to a battery from a light bulb would have less current than
the outgoing terminal. There has to be a third path to allow current to
divide, but the totals of the division equal the initial amount. That's
a rule we learn way back in basic electricity. Current or charges are
not converted into heat.

Radiation is no different. Radiation is not conversion of charges into
a force that allows action at a distance. Radiation is a force on other
charges at a distance caused by charge acceleration.

The only thing that allows an antenna to have current taper or current
change along the length of a wire suspended in space is displacement
current. It is not standing waves, it is not radiation, it is not
resistance.

Of course we could add a shunt resistance or inductance to provide a
path, but when there is no leakage resistance or shunting inductance
the path can only be what is called displacement current.

A series impedance or resistance by itself, even if the cause is
radiation or loss resistance, cannot cause current reduction with
distance along a conductor.

A model that only considers reflected and forward "waves" is fine, if
applied correctly. Cecil doesn't even seem to understand current, and
appears to think there is a forward current and reflected current
moving in opposite directions at the same instant of time in the very
same location in a conductor.

Wave theory is just fine, but it has to be understood it is just a
modelling shortcut and the results cannot conflit with basic laws of
physics. The current we measure with a clamp on meter IS the current
that causes radiation, standing waves or not. It is also the current
that causes all of the heating. We cannot really have two opposite

directions of charge movement at the same time in a single conductor.

Note that is not a measurement - that is what EZNEC reports but
let's assume, for the sake of discussion, that it is correct. W8JI
measured a 3nS, 4 degree phase shift in a coil twice as long with
43% more inductance. A bigger coil would obviously have a bigger
phase shift because of less current field linkage between the end
coils. So even if the phase shift through the coil is 10 degrees
as reported by EZNEC, W8JI's phase shift measurements were probably
off by *MORE THAN 200%* and that's why Tom is wrong.

> This same coil resonated an antenna with a whip length of 10 feet or so.

> antenna would be around 75 degrees.

You are confused. Some time ago, I explained why a mobile antenna
may not be 90 degrees long at all. Did you understand that posting?
All we can say is that (Vfor+Vref)/(Ifor+Iref) is purely resistive.
We don't know how many degrees the reflected wave has traveled in
its round trip because there are too many variables.

So please stop the diversions. I have always said that the delay
through a coil *IS WHAT IT IS* but it is NOT zero and it is not the
3 nS measured by W8JI for that 100 uH coil. It is also not the near-zero
phase shift measured by W7EL using standing wave current phase as the
reference. You, yourself, implied that is an invalid measurement when
you told us there is no phase information in standing wave phase.

Seems to me you are making my argument for me and that your real
argument is with the other side. Have you told W7EL that standing
wave current phase cannot be used to measure the delay through a
coil?

w8ji@akorn.net wrote:
> Radiation does not cause current taper. Dissipation does not either.

Radiation and dissipation are considered to be losses in a
transmission line covered by the attenuation factor. All that
is needed to prove your above assertions to be false is to
quote a transmission line equation. It can even be the more
simple flat form where the SWR is 1:1. Here it is in ASCII:

I = Im*e^(ax)*e^j(wt-bx)

Note this is the equation for *CURRENT* where 'a' is the attenuation
factor. The attenuation factor includes radiation and dissipation.

Your statements indicate a high level of ignorance. Assuming a flat
transmission line with an SWR of 1:1, if the loss in the transmission
line is 3 dB, we can put 200 watts into 50 ohm coax at the source end
and get 100 watts out at the 50 ohm load end. The current out of the
source is SQRT(200w/50) = 2 amps. The current through the 50 ohm load
is SQRT(200w/50) = 1.414 amps. The current has dropped from the source
to the load by exactly the same percentage that the voltage has dropped.

What you seem to be missing is that the H-field is attenuated by the
same amount as the E-field while the ratio of E-field to H-field
remains constant and equal to Z0. Current is proportional to the
H-field and voltage is proportional to the E-field.

Cecil,

As usual, you evaded the question, but this time you did not even do a very slick job of evasion.

The question is what happens to the 75 degrees that was formerly represented by the now-replaced wire. The coil may offer about 10 degrees.

I believe that Tom is stating that 75 is not equal to 10. Sounds like a reasonable statement to me.

I don't know why you are so worried about the precise details of phase measurements. Even your standard of precision, +/- 59%, won't make 10 equal to 75.

Cecil,

Wow! I think you may have set a new world record for the most irrelevant concepts per word dragged into an RRAA posting.

We got transmission lines, attenuation factors, H-fields, E-fields, and even SWR. Not to mention watts, dB, and Zo.

It is truly unfortunate that none of this is connected to the subject at hand, displacement current, but it makes for a colorful message.

I've said it before and I'll say it again, there is no phase variable
in I1*cos(kx+wt) and there is no phase variable in I1*cos(kx-wt) so
there can't possibly be any phase information in 2*I1*cos(kx)*cos(wt).
If you're going to measure a phase difference between two places on
a transmission line and you want to write an equation describing what
you're doing, you have to have the phase variable somewhere in your
equation so you can solve for it. Also, it would help, Cecil, if you
would be a little more careful when you copy these equations from your
favorite Bible. They keep changing form as time passes.

I don't know what that has to do with displacement current, Cecil,
but if you're worried about it you can just use your coil at a frequency
where you get a more satisfactory current distribution. I made a coil
like you talk about (mine was 5.25 inches long,
27 turns, 6 inches in diameter) and it behaved pretty much like
a coil in parallel with a capacitor up to a few megahertz, at least.
Beyond that, it was a different story.

Tom,
So, you don't need to have standing waves on the resonant radiator?
If you see antenna and loading coil in it as coil in a closed circuit and not as resonator with standing wave, then you are off the rocker.

You don't know what the impedance is.
You don't want to repeat tests that W9UCW did.
You don't want to explain W5DXP models and answer his questions.
You don't want answer my question, but resort every time into "lessons" about your misconceptions.
I tried to go step by step, starting with resonant quarter wave and current distribution along its length, but you get off on your lecture tangent to muddy the waters and how you can make a coil that will have difference in current, while you stated at the begining that the current is ALWAYS the same. Now the stray capacitance can suck the current out of the antenna?
Read Kraus what he says about antenna (resonator), standing wave and energy in it. You can measure it, just as W9UCW did.
Keep it up!

73 Yuri

I just pointed out that Belrose apparently started this misconception in his 1953 QST article, got perpetuated in ham literature until it hit us in the face and we pointed out that it is wrong and now has impact on modeling and antenna design. Garbage in - garbage out. We are trying to correct it and show what the reality is.

you can make a ground rod pounder by coupling several short section of pipe
together. the ground rod is inserted into the pipe which keeps the rod from
bending. as the rod is driven into the ground sections are removed one at a
time until the rod is at sufficient depth.

it's getting it out thats the trickey part :)

Place a clamp on the exposed end of the rod and connect it to an
automobile bumper jack, the old fashioned kind that actually fit the
bumper. Jack the jack and it will pull the rod out of the ground. As it
appears you can reposition the clamp and lower the jack to another lift
point. Wa la one out of the ground ground rod.

Please don't tell us that you don't understand how the attenuation
factor in a transmission line current equation causes the current
to drop along the line equaling the percentage drop in the voltage.

One can write a similar equation for a standing wave dipole.

Tom, W8JI wrote:
"Wave theory is just fine, but it has to be understood it is just a modeling shortcut and the results cannot conflict with the basic laws of physics,"

The Quantum theory may replace the wave theory some day, but the wave theory has always satisfied my needs.

Terman writes on page 84 of his 1955 edition:
"The quantity aq. rt. of ZY is called the propagation constant of the line. It is a complex quantity, having a real part alpha called the attenuation constant and an imaginary part beta termed the phase constant."

On the next page 85, Terrman has diagrams showing behavior of the voltages of the incident and reflected waves on a transmission line. It is the same as that on antennas. That`s why the antenna section of Terman`s book tells the reader to refer to the transmission line chapter for the behavior of antennas. It`s identical.

I`ve erected and operated countless rhombics in the international broadcasting service. I`ve underloaded them and overloaded them and in the process melted plenty of dissipation lines. I can attest that Terman has it right. Sometimes you have to do what you`ve got to do even when you know better.

When the dissipation line went away we would cover outh America as well as Central Europe and get lots of fan mail for our troubles. We shouldn`t have been getting fan mail from South America but lots of Central Europeans were living there as refugees from the Axis and from the Allies. When we covered South America, some broadcaster with a valid claim on the frequency at that hour and place was being clobbered by us.. We couldn`t help it. Our job was to save the world and we did it while sometimes stepping on others in the process.

I guarantee we never put anything even close to 100KW into a dissipation line. Problem was the Signal Corps rhombic kits were maxed out at 5 KW and it took time to get bigger resistance wire. 100 KW in a dissipation line would have melted it in days if not sooner. As it was, standard G.I. lines lasted weeks while glowing a cheerful red and did not erupt in a blinding flash.

The wave travels along both wires simultaneously. The wires in the dissipation line melt at the input end not at the far end where the wire is smaller. Current does not travel through the line like the utility power frequency through a string of Christmas tree lights.

Tom needs to get with the reality of the program. His idea is seriously flawed.

Best regards, Richard Harrison, KB5WZI

Sorry, you are wrong about that. EZNEC reports that phase information.
Assuming the EZNEC default convention, the source is 1.0 amp at zero
degrees at t=0. So the RMS value of the traveling wave current is
1.0 amp at -'kx' degrees. -'kx' *IS* the phase angle of the current
up and down the wire referenced to the source. It is negative because
the source naturally leads the traveling wave.

Note 'kx' is how far the point of interest is away from the source
in degrees.

Doesn't anyone understand phasors anymore?

No argument from me. Obviously you didn't understand my previous explanation that a resonant mobile antenna doesn't have to be 90 degrees long - something I explained weeks ago. Therefore, the coil doesn't have to be 75 degrees. Please re-read my postings again below until you understand what I said.

Think of all the possibilities that make (Vfor+Vref)/(Ifor+Iref) purely resistive without any one of those terms being in phase with any other of those terms. Then you will realize why that mobile antenna is probably not 90 degrees long at all.

In my earlier posting, I gave values of phase that make the feedpoint purely resistive without any one of those terms being in phase with any other one of those terms.

BOTTOM LINE: Until you can prove that a mobile antenna is 90 degrees long, your argument is just another straw man. What is it about my following previous statements that you don't understand?

What I see in a lot of commercial installations is a Yagi with a boom that's longer than it needs to be for the antenna itself, sticking out the "back" past the reflector. That part attaches to the mast. If you had a very long boom, you might want to counterbalance it with something if you did it that way, and you might want some way to support the end of the boom, like a non-conductive line up to the top of the mast. The feedline in an installation like that would go back along the boom to the mast, and then down.

Cheers,
Tom

Say I was using a short wave receiver, and I'm on the second floor, without a good ground. I would be running a long wire. Would it help to cut a counterpoise for the bands I wish to listen to, a single wire for each band? Would it be 1/4, or 1/2 wave?

I take it you are saying you think current can flow two directions at the same instant of time in a conductor, can be "lost" from a single conductor through radiation and resistance without a shunting impedance, conservation of charge isn't important, and Maxwell's equations are wrong.

You know that because you installed antennas at one point in your life. Is that correct or did I misunderstand your post?

W8JI is confused above. Wave theory, i.e. the distributed network
model, is not much of a modeling shortcut. The lumped-circuit
model is the actual shortcut and is a subset of the distributed
network model. The lumped-circuit model conflicts much more
with Maxwell's laws than does the distributed network model
which conflicts hardly at all.

EM energy is certainly flowing in two directions because it is
a standing wave antenna. The forward current phasor is proportional
to the forward H-field. The reflected current phasor is proportional
to the reflected H-field. The two H-fields are superposed. That is
the same thing as adding the two current phasors.

Quoting Balanis: "Standing wave antennas, such as the dipole,
can be analyzed as traveling wave antennas with waves propagating in
opposite directions (forward and backward) and represented by
traveling wave antenna currents I(f) and I(b)."

W8JI says an antenna cannot be analyzed in that way. Who are we
to believe? Balanis or W8JI?

Balanis gives us permission to analyze two currents flowing in opposite
directions at the same time. After all, the superposition principle
allows us to do that. I'm sure Dr. Balanis would like to hear your
argument to the contrary.

Kraus agrees with Balanis and disagrees with you. "A sinusoidal
current distribution may be regarded as the standing wave produced
by two uniform (unattenuated) traveling waves of equal amplitude
moving in opposite directions along the antenna."

W8JI says it cannot be regarded in such terms. Who are we to
believe? Kraus or W8JI?

> ... can be "lost" from a single
> conductor through radiation and resistance without a shunting
> impedance, conservation of charge isn't important, and Maxwell's
> equations are wrong.

All we are saying is that the currents drops the same percentage
amount as does the voltage. Voltage and current share the same
identical attenuation factor. The E-field and H-field drop by the
same percentage. If your model absolutely requires a shunt
impedance, it can be found in the distributed LCLCLCLCLC model
of a transmission line.

Conservation of charge and conservation of energy are inviolate.

Maxwell's equations, as opposed to the flawed lumped-circuit model,
are correct. The distributed network model is a lot more like
Maxwell's equations than is the lumped-circuit model.

I tried to make the same antenna with 1/2" hardline & had several RF analyzers to help me, it never worked out. This article helps explain why coax wont work, I used wire and would my on coils for phasing, i also took apart a Madrax antenna to get the measurements, they used brass tubes inbetween the coils, not because its brass but so the 1/2 wave length can be easily adjusted.

> There are other programs which go down to audio and power frequencies.
> ----
> Reg, G4FGQ
[snip]

It's a pity that your programs don't work all the way down to DC.

Maxwell's celebrated [I really should say Heaviside's] equations do!

Aside: It is Heaviside's vector formulation of Maxwell's complicated quaternic formulation with which most of we [modern] "electricians" are most familiar.

In fact the common/conventional mathematical formulation of the reflection coefficient rho and its' magnitude gamma as derived from the Maxwell/Heaviside equations are indeed valid from "DC to daylight".

Notwithstanding the views of some, there are indeed "reflected waves" at DC and even these "DC reflections" are correctly predicted by the widely accepted and celebrated common/conventional mathematical models of electro-magnetic phenomena, formulated by Maxwell and Heaviside.

Reg I assume the reason for your programs failure to give [correct] answers below 200 kHz is because your "quick and dirty" programs do not utilize full mathematical models for skin effect below 200 kHz. As you know, solving Maxwell's equations for analytical solutions of practical problems is fraught with great difficulties and so often numerical techniques [MoM, FEM, etc...] or empirical parametric methods are used.

Most [non-parametric] analytic skin effect models derived from Maxwell and Heaviside's equations [such as those in Ramo and Whinnery] involve the use of "transcendental" functions that although presented in a compact notation, even still do not succumb to "simple" evaluation.

Surely though skin effect is easier to model below 200 kHz where the effect becomes vanishingly smaller? And so I don't understand why your programs cannot provide skin effects below 200 kHz.

If you are interested I can point you to some [lumped model] skin effect models for wires [based upon concentric ring/cylindrical models] that, although parametric and empirical, are very "compact" and easly evalutate

and which closely model skin effect, and other secondary effects such as "proximity crowding", up to prescribed frequency limits as set by the "parameters".

These models simply make empirical parametric corrections to the basic R-L-C-G primary parameters by adding a few correction terms.

Thoughts, comments?

Roy:

Yes, that's why "gapped" cores must be used for precision [inductance] work.

The properties of the basic core materials are too difficult to control during manufacture and hence result in manufactured pieces of wide variability. In addition the basic core material properties exhibit a wide variation under environmental variations such as temperature, pressure, etc...

Inserting an accurately calibrated air gap in the magnetic path, by grinding the pot core center posts to a specific Al or alpha, accurately regulates the overall reluctance of the magnetic path and overcomes both of these variable effects, it alsow and allows the engineering of high performance "precision" inductors. In addition the air gap also mitigates a lot of the non-linear effects noted at higher levels of flux density.

Gapped cores are "de riguer" for precision work. Ungapped cores are only used for "sloppy" inductance work. This includes many applications of transformers as well.

840. Yet another microwave question

Newsgroup: rec.radio.amateur.antenna
Date: 2006-04-11 13:43:37 UTC
From: Ken Bessler <kg0wx@NOSPAMyahoo.com>
Message-ID: <noO_f.1069$B42.731@dukeread05>
Source record: 61082

I'm upgrading my laptop's antennas to 15" long 7dbi gain monsters (2).
I don't have the materials (connectors) to do the job right so in true ham
fashion, I cobbled up a solution:

I have a 1.37mm od 50 ohm feedline (excellent quality) going up the
back of my screen. Currently I have the braid/center separated at the
end and soldered to my antennas. The new antennas have rp-tnc
connectors and I don't have the proper bulkhead connectors for them.

I found that a spare component (barrel diode) lead is a nice press fit
for not only the center socket on the antenna but also for the shield so
I plan on inserting the wire where it goes and soldering the coax to the
wires. This will result in 2mm of distance between where the coax is
stock (unseperated) and the new antennas' rp-tnc connector.

Now - if I used bulkhead solder rp-tnc connectors, I don't think I could
get that 2mm any smaller. As a matter of fact, I suspect, looking at
Amphenol's specs, the new distance where the coax is separated would
be greater. I can find no rp-tnc connectors for my micro coax so that's out.
I've got to solder. I've seen many examples of where feedline is fed to
a bulkhead connector like this, and sometimes they have 12mm of separated
line but that was in a VHF application.

So my question is this: If I keep my separated coax run (between the end of
the coax and the rp-tnc antenna connector) to 2mm or less, what will that do
as an impedance bump or otherwise at 2412 mhz? How critical is it at these
freqs?

Thanks for the help!

Tom, W8JI wrote:
"I take it you are saying you think current can flow two directions at the same instant of time in a conductor through radiation and resistance without a shunting impedance, conservation of charge isn`t important, and Maxwell`s equarions are wrong."

That`s the wrong take.

Maxwell works for me even if there is no aether.

Anntennas work in free space without a ground but it is hard to duplicate free space conditions at high and lower frequencies here on earth.

Every standing-wave antenna has a reflection caused by an impedance discontinuity at wire`s end. At this point, a reflection begins its travel back toward the generator. By the time the reflection arrives at the generator, every point on the wire has current flowing in both directions simultaneously. No shunting capacitance to earth or anyplace else is needed to conserve charge. The wire is self-sufficient.

Radiation resistance is a convenience defined as the resistance which if placed in series with an antenna would consume the same power that the antenna is radiating.

At every point along an antenna with a reflection, current is flowing in two directions at the same time.

Best regards, Richard Harrison, KB5WZI

Gene Fuller wrote:
> Does that end the thread?

Does agreeing that 75 is not equal to 10 end the thread?
Of course not. That posting *ASSUMED FOR THE SAKE OF
DISCUSSION* that EZNEC was reporting the actual delay
through the coil. I suspect it is not reporting the
actual delay because reflections are still present
inside the coil. The characteristic impedance changes
abruptly at the top of the coil so that would be no
surprise at all.

We know EZNEC blindly reports the net current that is
there. If we, as modelers, don't eliminate reflections,
EZNEC will not correctly report the traveling wave phase
shift. In our naivete', we didn't eliminate reflections.

75 degrees is probably not correct. 10 degrees is
probably not correct. Why do you want to quit before
the correct answer has been found?

****
Here's a more valid procedure for determining the
delay through a coil. Changing nothing except the
number of turns, add turns until the coil is self-
resonant at the frequency of use. Frequency doesn't
change. Coil diameter doesn't change. Turns per inch
doesn't change. The *ONLY* thing that changes is the
length of the coil. At self-resonance, we *know* the
longer coil is 90 degrees long.
****

Take that same 32 turn coil and keeping everything the
same, add turns to the coil until it is self-resonant.
We haven't changed the frequency, the diameter, or the
turns per inch. All we have done is add 37 turns to the
original 32 turn coil to make the self-resonant frequency
equal to 4 MHz with 69 turns. SINCE WE HAVEN'T CHANGED
THE FREQUENCY, WE KNOW THAT THE VELOCITY FACTOR OF THE
COIL HAS NOT CHANGED.

In the velocity factor equation, the only variables are
coil diameter, turns per inch, and wavelength. NONE OF
THOSE VARIABLES ARE CHANGED ABOVE.

So we know that 69 turns makes that coil stock self-resonant
at 4 MHz. That would make the phase shift through 32 turns
equal to 42 degrees, making our above 10 degree assumption
false. 42 degrees is probably fairly close to the actual value.
The velocity factor for that coil stock calculates out to
be 0.023 on 4 MHz.

The delay through a coil is what it is. The only valid side
to this argument are technical facts, valid measurements,
and valid modeling.

Completely wrong, as usual. There is nothing in the natural world
that can double itself and go two opposite directions at the same
time. In order to do so it would have to violate the principle of
the conservaton of charge. At any instant, the charge at a point
has to be going either one direction or another which you can
confirm using the wave equation which Cecil doesn't understand
any more than you do. Superposition is a fine principle, but
like any intellectual tool it has to be understood to be used
properly.

If you are using long wire for different bands, you can tap to your water pipe for ground, or metal frame of the screen door, or most likely your RX is already "grounded" through its AC PS. You can try through capacitor of about 10000 uuF/1kV from your RX ground to your ground pin the AC outlet. Alternative I used for antenna when in restricted area, just run wire from ant terminal on RX through capacitor of about 10 k rated at least at 3000V to one of the connections in AC outlet, well insulated and mounted in AC plug.

It's clear to me that Richard can quote references and cite anecdotal evidence from his own work. What's not clear to me is that Richard has read and understood what W8JI actually wrote.

I would ask if he believes in the physical reality of charge, but suppose that's not at issue here.

Instead, I'll simply point out that there is NO fundamental disagreement between what Tom wrote and:
--properly developed theory based on standing waves
--properly developed theory based on travelling waves
--properly developed TEM transmission line theory
--Schelkunoff's antenna mode theory
--the King-Middleton second-order (antenna) theory
--even the work of Gauss, Ampere, Faraday, Maxwell et al.

It's like Ian White _tried_ to point out some postings ago, any theory which is seriously enough at odds with reality is not likely to be useful; but all that theoretical development is NOT at odds in the VLF/LF/MF/HF/VHF/UHF world we customarily deal in, and certainly not with what Tom wrote.

That current on a transmission line tapers as you get further from the source is no surprise, but in no way does it conflict with what Tom wrote. Anyone familiar with basic electronic components should have no trouble understanding that, thinking about it simply from the point of view of charge, and how it moves. A degree in electronics is not required.

Understanding the congrence among many methods/theories is a very nice thing, for it gives one confidence that they are correct, and the ability to apply the one that's most convenient to any particular problem. I would not want to take away wave theory, or any other valid theory, from you; I would only ask that you better understand that your pet is not the ONLY valid explanation.

And THAT in now way condones some of the terrible misrepresentations of valid theories that I see here. But again, if you understand how various valid theories are congruent, you're in a much better position to spot the misrepresentations.

Cheers,
Tom

The Quantum theory may replace the wave theory some day, but the wave theory has always satisfied my needs.

Terman writes on page 84 of his 1955 edition:
"The quantity aq. rt. of ZY is called the propagation constant of the line. It is a complex quantity, having a real part alpha called the attenuation constant and an imaginary part beta termed the phase constant."

On the next page 85, Terrman has diagrams showing behavior of the voltages of the incident and reflected waves on a transmission line. It is the same as that on antennas. That`s why the antenna section of Terman`s book tells the reader to refer to the transmission line chapter
for the behavior of antennas. It`s identical.

I`ve erected and operated countless rhombics in the international broadcasting service. I`ve underloaded them and overloaded them and in the process melted plenty of dissipation lines. I can attest that Terman
has it right. Sometimes you have to do what you`ve got to do even when you know better.

When the dissipation line went away we would cover outh America as well as Central Europe and get lots of fan mail for our troubles. We shouldn`t have been getting fan mail from South America but lots of Central Europeans were living there as refugees from the Axis and from the Allies. When we covered South America, some broadcaster with a valid
claim on the frequency at that hour and place was being clobbered by us.. We couldn`t help it. Our job was to save the world and we did it while sometimes stepping on others in the process.

I guarantee we never put anything even close to 100KW into a dissipation
line. Problem was the Signal Corps rhombic kits were maxed out at 5 KW and it took time to get bigger resistance wire. 100 KW in a dissipation line would have melted it in days if not sooner. As it was, standard G.I. lines lasted weeks while glowing a cheerful red and did not erupt in a blinding flash.

The wave travels along both wires simultaneously. The wires in the dissipation line melt at the input end not at the far end where the wire
is smaller. Current does not travel through the line like the utility power frequency through a string of Christmas tree lights.

Tom needs to get with the reality of the program. His idea is seriously flawed.

Best regards, Richard Harrison, KB5WZI

Richard H.,
He is stuck on DC in a coil. Tom did not discover Standing Waves,
Impedances, Currents, Voltages in RF circuits, antennas, feedlines.
Heloooo! IT'S RF and standing waves along the resonant antenna and things
to do with RF energy along them radiators, like sin and cos distribution of
voltage and current. Which show that current and voltage can be ZERO along
the conducting wire, aka antenna. First he used Kirchoff, now is Maxwell to
the "rescue" to muddy the waters.
Maybe we should apply for him for vanity callsign WR0NG :-)

Could you please enlighten us, Cecil, exactly why you think that
anything in all of W8JI's full posting referenced by reference below
where he implicitly or explicitly says anything at all about a lumped
model, or about lumped behaviour? After a careful search, I'm unable
to find it. I only find a discussion of distributed behaviour in a
circuit which extends beyond near field.

Cheers,
Tom

(On the other hand, all the wave and field theory I know was developed
to explain and model the forces among charges, and the reaction--the
motion and accumulation--of those charges as a result of those forces.
That's EXACTLY what I DO see W8JI writing about in the referenced
posting.)

W8JI is confused above. Wave theory, i.e. the distributed network
model, is not much of a modeling shortcut. The lumped-circuit
model is the actual shortcut and is a subset of the distributed
network model. The lumped-circuit model conflicts much more
with Maxwell's laws than does the distributed network model
which conflicts hardly at all.

Tom Donaly, KA6RUH wrote:
"There is nothing in the natural world that can double itself and go in the opposite direction at the same time."

Watch water waves slam into a bulkhead and you can see the reflected waves interfere with the incident waves as they travel in the opposite directions.

Electrical waves, incident and reflected, pass through each other too. In the antenna or transmission line, the charge is impelled by the energy supplied by the generator to move back and forth on the surface of the wire at the radio frequency rate.

The incident wave and the reflected wave on a transmission line travel in opposite directions. At certain points along the line the voltages in the waves will be in phase and will add, while in other points they will be out of phase and subtract. The points along the line where the two voltages are in phase are points of maximum voltage and minimum current and are spaced one half wavelength apart. The points along the line where the two voltages are 180-degrees out of phase are points of minimum voltage and maximum current and are also one half wavelength apart. The distance between alternate points is one-quarter wavelength.

The reflection of a radio wave is a natural occurrence. When the voltage produced by the incident wave hits the open-circuit of a wire it doubles itself and starts a wave propagating in the opposite direction while the incident waves are yet arriving at the open-circuit.

Best regards, Richard Harrison, KB5WZI

Tom

Have you ever sloshed water in a bowl? If you had you would have seen wave forms going in both directions. First the initial wave crosses the bowl then reflects off the side of the bowl and returns in the opposite direction.
This is the same as an EMF wave in an antenna. No violation of any principles of conservation, in fact it is demanded of the principle.

Calculation of skin effect in a round wire is simple, provided that you have the ability to calculate various Bessel functions. Libraries in Fortran are widely available, and probably in other languages also. NEC-2 (and therefore EZNEC) does such a full calculation for evaluation of wire loss. A side benefit of doing this is that you also get an accurate evaluation of the internal inductance. However, in practical terms, you can do quite well with the common skin depth approximation based on the assumption that the wire diameter is at least several skin depths, and an interpolation from there to the DC case.

Coaxial cable is more problematic than twinlead. Most analyses assume that the resistance of the shield is negligible. But for an accurate evaluation, you need to include it. At high frequencies it's simple, but it's much more difficult at low frequencies than for a round wire, since most equations you'll find require subtracting huge numbers from each other, exceeding the capability of even double precision on modern PCs. It's possible but requires some mathematical manipulation and trickery.

With coax at low frequencies, the fields from the two conductor currents reach the outside of the cable. While they should still cancel, this might cause some problems with the assumptions we normally make in the analysis of coaxial transmission lines.

You're not likely to be able to do a very good job of predicting real life transmission line behavior in any case, though, unless you account for such real factors as the roughness of stranded conductors, braided coax shield, and plated conductors. I'd also expect twinlead with solid or punched polyethylene insulation between conductors to be somewhat dispersive (that is, having a velocity factor which changes with frequency), but I've never tried to measure it. Reg has said he's measured many pieces of real cable and found its loss to agree with his earlier coax program, but won't tell us where he buys it. Everything I've ever been able to buy is considerably lossier.

This is simply one more example of the seduction of other-
wise intelligent people by the lumped-circuit model's
unproven presuppositions.

You are confusing charge with EM wave energy. If two EM light
waves traveling in opposite directions can cause a standing
wave in empty space, then so can two RF waves traveling in
opposite directions in space or around a wire. There is no
requirement for current at all. Current is a left over
artifact from the DC model. In fact, it can be proven
that virtually all of the energy (power) exists solely in
the two EM waves surrounding the wire and virtually none in
the conductor. All that is required for standing waves is
E-fields and H-fields traveling in opposite directions WHETHER
A WIRE EXISTS OR NOT.

If everyone were using Maxwell's equations instead of flawed
simplified models, none of this confusion would exist. All
of the energy is in the waves and none in the current or
voltage. After all, E x H is the *total power* in a wave.
There is no extra energy left over to support voltage and
current.

Dave,

You have highlighted a misconception that is common and a great cause of confusion in this forum.

Yes, the "waves" can do what you say. However, the "waves" are merely mathematical descriptions of the underlying physical phenomena. There is simply no such thing as a "wave" all by itself. Instead there are water waves, electromagnetic field waves, guitar string waves, sound waves, and so on.

Nature tends to be single valued, at least in the ordinary classical world. At any specific point in time and space there is only one value of current, one value of electric field, one value for the motion of a particle (water molecule, guitar string molecule, etc.), one charge density, and so on. These values can and do change with differences in time and space. However, the physical entities do not have two values at once in the same time and place.

The point is that in any disagreement between the lumped-circuit
model and a properly applied distributed network model, the
lumped-circuit model loses *EVERY* time since the lumped-circuit
model is a *SUBSET* of the distributed network model.

If your current charge concepts disagree with Maxwell's equations,
Maxwell's equations win *EVERY* time. Maxwell's equations do not
require individual charge carriers. They work just fine considering
only fields in the aether.

Hi Tucker

Thanks for reference to that great site. I really like that flat antenna.

Jerry

W8JI is right 99% of the time. I agree with him on those
things as do you. Your above posting is no surprise.

Here's one of W8JI's statements. Please defend it.

>W8JI said:
> > Radiation does not cause current taper. Dissipation does not either.

What is contained in the attenuation factor for the current
transmission line equation if not radiation and dissipation?
What else is there?

That appears to me to be the most valid measurement that we
can make of the delay through a coil. If you have a better
way, please present it.

Gene, W4SZ wrote:
"However, the physical entities do not have two values at once in the same time and place."

You can measure each of the two simultaneous constituents with the right equipment. A Bird Thruline wattmeter uses a directional coupler to separate forward direction power from reverse direction power. These are obbtainable at the same time and place anywhere in a 50-ohm coax line. Individual volts and amps in each direction are easily calcuable from the powers indicated in each direction.

Best regards, Richard Harrison, KB5WZI

Cecil,

C'mon, you know as well as anybody that inductance of a coil tends to increase as n-squared. Yes, there are all kinds of special cases and correction factors.

Adding turns and then pretending everything is nice and linear, thereby allowing decomposition into subcomponents, is just plain silly.

Cecil, can I infer from your reply that you, too, can't find anything
in W8JI's original posting that refers to a lumped model?

With respect to your request, I suggest you re-read Tom's whole posting
and see if you can understand it. W8JI should perhaps have included in
the statement you quoted, "in and of itself/themselves," but certainly
it's accurate in the context from which you've extracted it. Certainly
you can have "current taper" along an antenna or along a TEM
transmission line for reasons other than loss to radiation or heating,
and ALL of them go right back to the very basics of what's going on in
an antenna and in a transmission line, and what Maxwell et al were
explaining with all their work.

Cheers,
Tom

Cecil,

I think I specifically mentioned the "ordinary classical world", but I'll play along. Why don't you go ahead and measure that electron to prove that it goes through both slits at once? 8-)

Gene, W4SZ wroyte:
"However, the physical entities do not have two values at once in the same time and place."

All that is needed to prove energy in the incident and reflected waves each has its own values is to separate the two with a directional coupler as the Bird Thruline wattmeter does. It gives you forward and reverse powers at the same place anywhere you choose along a transmission line. The standard device is calibrated for 50-ohm lines so it is easy to convert the power indicationsw to volts and amps if desired.

Take what Tom, W8JI wrote today:
"I take it you are saying you think current can flow in two directions at the same instant of time in a conductor, can be "lost" from a single conductor through radiation and resistance without a shunting impedance, conservation of chrge isn`t important and Maxwell`s equations are wrong."

Of course, except for Maxwell!

Maxwell`s equations work.

Current can flow in opposite directions past a point.

Shunting impedance makes a voltage divider with series impedance, but that`s not the only way to get a difference between points on a conductor or a coil.

Conservation of charge isn`t an issue with r-f current in a wire or coil.

Tom`s posting is nonsense.

Best regards, Richard Harrison, KB5WZI

Source record: 61114

Hi Bob,

Ground losses aren't extremely important for receiving applications. A few extra feet of depth of ground rod isn't going to make any difference, because the RF doesn't flow 8 feet down, or 5 feet down, but more flows on the surface of the ground and/or some inches down (depending on your ground conductivity profile)

As such, you could try a 4 or 5 foot ground rod.

If you want a no-pounding solution instead, lay down a few radial wires. The length and number aren't critical. Try four or eight wires each 1/8 wavelength long at the lowest frequency of interest.

If the noise in your receiver doesn't increase when you plug the antenna into the RX , then you may want a better ground system. If the noise DOES increase, then your noise floor is that of the natural/artificial noise that your antenna is picking up, and more raw signal from the antenna won't help anything. (Though moving the antenna around might).

Cecil, WHAT is your hangup about "lumped-circuit"?? W8JI-Tom, Tom Donaly, Ian White, Roy Lewallen, Gene Fuller, Reg Edwards, I, and others I can think of are NOT, repeat NOT, absolutely NOT, most definitely NOT, talking about a lumped-circuit model. A lumped-circuit model in general does NOT (repeat all the above emphasis) talk about individual charge carriers, and individual charge carriers are NOT required to talk about all the things we've been saying. Egad, man.

I will repeat, Maxwell et al were working to explain the forces acting on charge, and the response of charge to those forces: the motion of charge, the acceleration of charge, the accumulation of charge. Fields, both electric and magnetic, are simply a mathematical and useful way to represent the forces caused by all charges (in motion, accelerated, at rest) on all other charges in the universe. Sometimes fields as developed in classical electrodynamics fail to accurately represent our observed reality, but they are still useful in describing a great many of our everyday observations, and in solving many--essentially all--of our everyday antenna problems.

I won't say it didn't happen at all, but I certainly can't recall in any of these "discussions" getting down to considering individual charged particles. We're dealing with effects accurately represented by charge expressed as a continuum, distributed over space, with abrupt boundaries at the edges of conductors assuming the forces aren't great enough to rip free charge loose from the wires and form corona. We are dealing with quanta in such overwhelmingly great numbers and such small energy per quanta that there's no point in discussing them as quantized charge or photons. No, we're dealing with a linear system that's sufficiently accurately represented by a set of differential equations that all get back eventually to the interaction of a continuous distribution of charge, not a "lumped circuit" OR individual charged particles, which are themselves very different thing, even though we know that our distribution of charge is made up of such particles when viewed on a fine enough scale.

So, PLEASE wake up and quit trying to attribute this "lumped circuit" stuff, and the completely independent charge quantization stuff, to this discussion. It simply is NOT there. It is absolutely NOT the point of all this.

Cheers,
Tom

> pet is not the ONLY valid explanation.

The point is that in any disagreement between the lumped-circuit
model and a properly applied distributed network model, the
lumped-circuit model loses *EVERY* time since the lumped-circuit
model is a *SUBSET* of the distributed network model.

If your current charge concepts disagree with Maxwell's equations,
Maxwell's equations win *EVERY* time. Maxwell's equations do not
require individual charge carriers. They work just fine considering
only fields in the aether.

Tell me which of the water molecules moved in two opposite directions
at the same time. The waves can move through each other in opposite
directions, but their combined influence is what moves the water
molecules. There are not two separate sets of water molecules that
flow in opposite directions, either. It's the combined total of
forces that causes the movement of both charge and water. Two opposite
movements of either charge or water are impossible.

Peter, I am very familiar with what happens below 200 Khz.

Most of my transmission line progs cover from power freqs up to UHF.
And they only stop there because of problems with finding room on the
screen for numerical overflow and the programming trouble with
shifting decimal points around.

Very shortly I shall have a program about "Behaviour of Coaxial
Transmission Lines at Low Frequencies. It accepts frequencies in the
range 20 Hz to 5 MHz. Input data is kilo-Hertz in the range 0.02 to
5000. Originally I stopped at 500 KHz.

There's no point in extending frequency range up to 10 GHz because
there is no interest in the subject matter. Although the maths is
already built in. There's just not enough space on the screen.
Programs should be easy to use.

As a program writer yourself you should be familiar with all this.

Reg.

Source record: 61121

A bit further to this:

What should I do when I find that Maxwell's equations do NOT accurately describe the observable situation, with observations that can be easily repeated with the same results each time? What should I do about the fact that charge is indeed quantized if I look at it finely enough? What should I do about the fact that radiation is quantized if I look at it finely enough? Maxwell's equations don't account for or allow for those effects, respectively. Yes, I certainly accept Maxwell's equations as adequate to describe what I'm likely to see in any ham antenna I deal with, but at the same time, I realize that they are not the final word. What I WOULD like to get back to here is that all the theory I listed in the posting which precipitated all this, from Maxwell to King and everything in between, all agrees with how charge DOES behave well enough to be very useful. It's those abstractions which have been proposed which do NOT line up with those theories very well at all that I want to weed out. I'm for sure not going to use them, and I'd prefer to educate others to avoid them as well.

For anyone interested in looking them up, I believe it will be found that Maxwell's equations become very uninteresting if there is no charge and no motion of charge. Fields alone don't do it. It's those things--charge and motion of charge--embodied right there in the equations, that result in what we describe as fields around our transmtting antennas: electric, magnetic, and most interesting to us here, electromagnetic. And on the receiving end, it's the motion of charges in response to the fields that produce an interesting result.

In a posting with Message-ID:
<1144784891.274341.118940@z34g2000cwc.googlegroups.com>, I wrote, among other things,

"W8JI-Tom, Tom
Donaly, Ian White, Roy Lewallen, Gene Fuller, Reg Edwards, I, and others I can think of are NOT, repeat NOT, absolutely NOT, most definitely NOT, talking about a lumped-circuit model."

Belay that. It is not for me to say what others are talking about. I am sorry if any have taken it the wrong way. Please replace it with the more carefully worded paragraph below.

Cheers,
Tom

I am absolutely certain that I infer from the recent postings in this thread and other related threads that W8JI-Tom, Tom Donaly, Ian White, Roy Lewallen, Gene Fuller, Reg Edwards and others I can think of are NOT, repeat NOT, absolutely NOT, most
definitely NOT, talking about a lumped-circuit model. I know with equal certainty that I have not been, in any of my postings here. If what I have inferred is not what the original authors of those postings intended, I invite them to post whatever they wish to make more clear their intent or to expand on their previous posting(s). Obviously, they don't need my invitation to do so. If any of them does not wish their name associated with this thread, I invite them to quit posting to it and to revoke their earlier posts. Again, they obviously don't need my invitation to do so.

Increasing the length of a coil or transmission line doesn't
change its velocity factor at a fixed frequency.

> Adding turns and then pretending everything is nice and linear, thereby
> allowing decomposition into subcomponents, is just plain silly.

Velocity factor is *nice* and linear, i.e. it is constant.

Please stop these diversions. I'm sure you are not that ignorant.

Nobody is arguing about that so it is obviously just a straw man.
The real question is: Can two EM waves travel in opposite directions
in free space or along a wire. The answer is YES!!! Standing waves
can exist in free space or along a wire. To deny the existence of
standing waves is ridiculous.

You should find out what is wrong with those observations. Therefore,
you should find out what is wrong with W8JI's and W7EL's measurements.

> the powers indicated in each direction.

That's not true.

The directional coupler in a Bird meter samples the across vector
(voltage) from a capacitive divider and adds it to a sample voltage of
the through vector (current) from a current transformer in a
predetermined ratio. After that sum, the output is rectified.

I can place it in a system with NO standing waves and it will show
standing waves. I can place it in a system with standing waves and have
it show NO standing waves. It does not measure standing waves, it
simply measures the ratio and phase of voltage and current at one point
in the transmission line.

There can NEVER be current flowing at that point in two directions at
the same instant of time, and the Bird does not even contain a system
that samples standing waves.

Now I can build a piece of test gear that does directly read standing
waves, but it requires a line sampling lwength of at least 1/4 wl.
Such a device would be totally independent of the actual operating
impedance, and could read either current or voltage.

The Bird meter is NOT that type of unit.

That is an interesting hypothesis.

How would you go about testing its validity?

(Have you heard of end effects?)

Yes, but if it is calibrated for 50 ohms and installed in a 50 ohm
environment, it is indeed accurately reporting forward and reflected
power. It is accurately separating the forward wave energy from the
reflected wave energy. If it weren't, Bird would be guilty of false
advertising.

Since I know you are going to nit-pick that statement, I
probably should add "appreciably" in front of "change". :-)

> How would you go about testing its validity?

The velocity factor of a piece of transmission line doesn't
change appreciably with length. The velocity factor of a
straight wire doesn't change appreciably with length.

I would think that a two wavelength coil would be approximately
twice as long as a one wavelength coil which would be
approximately twice as long as a 1/2 wavelength coil.

The equation for the velocity factor of a coil depends upon:
1. The diameter of the coil
2. The number of turns per unit length
3. The frequency

None of those factors are dependent upon the length of the
coil.

> (Have you heard of end effects?)

Of course, it's the 5% difference between 468/f and
492/f. I'm not talking super accuracy here - just better
accuracy than anyone has yet measured.

It is akin to your suggestion that a coil be installed
between two current nodes and its number of degrees
calculated from that. I will try to take that same
coil that I have been talking about and use your
suggestion to see how close the results are.

However, I am preparing for a 6 state Harley road trip over
the Easter holidays and will not be back until Monday.

That`s close. In the cartridges is a loop terminated in a diode. Capacitive coupling of the loop to the center conductor of the precision ccoax supplies the voltage sample. Inductive coupling of the loop supplies the current sample.

I`ve described operation several times here and once in this thread, so I won`t repeat it.

SWR is easy to get from the forward and reflected indications of the wattmeter.

VSWR = 1 + sq.rt. (ref. PWR / for. PWR)
Divided by 1 - sq.rt. (ref. PWR / for. PWR)

Bird supplies a family of VSWR lines on a graph of forward power vs. reflected power for those who would avoid the calculation. They can also supply a slide-rule to do rhe same.

Best regards, Richard Harrison, KB5WZI

Yes, many, and they've been discussed here at length. That this concept is wrong can and has been shown by theory, modeling, and measurement. I made and posted measurements on this newsgroup in November 2003 which demonstrated clearly that the presumption is false.

The loading coil isn't making the antenna act like a physically longer antenna. In the extreme case of a physically short inductor at the feedpoint, it's simply modifying the feedpoint impedance and has no effect whatever on the antenna's radiation. As the inductor gets longer, it does become some part of the antenna, but adding an inductor which resonates, say, a 45 degree physical radiator doesn't make the antenna act like a 90 degree physical radiator.

> cons? are they used commercially?
>
> Than you.

Yes, They were fine. Worked well, practical, but heavy and took up a lot of "real estate" topside. Useful over the freq range 10-30 in most cases. There may be one or two left in the active Navy, but they have mostly been replaced by twin whips. I think USS Belleau Wood (decommissioned October, 2005) still had the discone/cage combination antenna at that time. The USS Missouri Memorial has one.

You need a sturdy center mast to support the cone section which is made of about 25 wires. It's about 25 ft tall. The disk is insulated and sits atop the mast. The advantage is that it's broadbanded. Good VSWR across the band. Not much use for hams, since we just have those little slices of the band. One vertical omni antenna has coverage just like all the other vertical omnis.

So, you might not want to bother, except for the fun of doing it and seeing that it works. I agree, that's reason enough for some, but it will be a lot of effort. ARRL Antenna Book covers it nicely, too, I see.

If you use a J-pole as the driven element of a yagi, it will not distort the pattern much at all. You can fasten the J-pole to the yagi boom 1/4 wave from the top of the J-pole and still excite it from the stub.

But being in a yagi will change the impedance of the J-pole so you will have to match it IN the yagi.

Another solution is to stack two smaller yagis side by side away from the mast.

There will still be distortion but these techniques can lessen it considerably.

We're all agreed on what happens with the Bird's sampling lines and detector. The only differences arise from each person's attempt to condense it all into a couple of sentences, and aren't worth arguing about.

But Richard cuts it too short when he claims that:
>>A Bird Thruline wattmeter uses a directional coupler to separate
>>forward direction power from reverse direction power.

That claim confuses two different things: what the line-loop-detector hardware physically *does*; and what the indicated results *mean*. The first of these is agreed; the second is not.

The disagreement is entirely about the interpretation - in other words, it's about the theory about standing and travelling waves. Richard habitually misses out this step, which makes it look as if the Bird wattmeter "proves" the physical existence of forward and reverse travelling waves of power.

It doesn't. Everything that you see printed on the Bird's meter scale, and in the Bird literature, represents that company's particular interpretation of theory about waves on transmission lines. The details of that theory are *not* agreed within this newsgroup, which means that - to some people - the two halves of Richard's claim do not join up.

> - 73 de Mike KB3EIA -

Every reason in the world. This misconception is EXACTLY what started this whole thing years ago.

The loading coil doesn't "replace" missing electrical degrees, it primarily corrects power factor by compensating reactance. Anything else is generally secondary, and is related to flaws in the system rather than something necessary.

That idea repeats one of the worse myths about loading coils.

The truth is the loading inductor almost never has the same phase shift in current as the missing antenna area it replaces, and it almost never has the same "current drop". "Current drop" isn't even a good English description of what happens in any circuit.

I can have an antenna of given dimensions with a loading coil at one fixed spot. The difference in current flowing into one end and out the other can go all over the place, depending only on the coil's physical design wity the antenna resonant on the same frequency. This happens ONLY by changing the coil.

If I had a coil that was compact and not against the groundplane with low stray capacitance compared to the antenna area above the coil, current difference between each terminal or through the coil could be immeasurable with reasonably good instrumentation. Phase shift in current could also be nearly zero. None of this would be anywhere near the area the coil replaces.

Without any change in anything except the coil, I could change all that. If I replaced the coil with a long stub or very large single turn, it would indeed act more like the antenna area it "replaces". The

reason for this is the coil's capacitance to ground and capacitance to space around the antenna, NOT the electrical degrees it replaces and certainly not the standing waves. This all can and has been proven over and over again. The very few people offering the long drawn out arguments against this really are violating basic electrical laws of how systems really work, and enforcing the myth that a loading coil is so many electrical degrees long or that displacement currents are not at work and current magically vanishes, or magically flows two directions at the same time at one point in a conductor.

A few people have taken the model of standing waves, not understood the limits or boundary conditions of that model, and thought it to be an actual literal description of what really is happening. They appear to actually think current can flow two directions at the same time at the same point. They somehow thing we can have charge drift velocity in two directions at the same instant of time at one point in a conductor, or that current can just vanish into thin air without actually being diverted through a second path.

A few people have violated the rules of charge conservation, charge movement, and misapplied the concept of standing waves, but the single largest error is standing behind the myth or misconception that that loading coil somehow acts like the "missing area of antenna".

I have a Comet CA-2x4SR 2m/70cm mobile antenna on a trunk lid mount. Comet tells me this is a "ground independent" antenna, so I've been thinking about adding a short mast to get it above the cars roof line. Will I gain or lose anything by raising the antenna above the ground plane?

I'm hoping raising it would give a more circular pattern by getting it above the roof line and above the 150/450 MHz scanner antenna mounted on the other side of the trunk.

Hey, Cecil,

In your two messages included above by reference, you complained that I had in the other two included messages put things you had written, but that I did not properly attribute them to you. I don't know whether to be offended, feel sorry for you, or laugh. In each of my two messages, immediately following my signature, is a line that begins, "Cecil wrote..." I trust it's not too difficult for most folk to understand, but I'll explain it for you. That line means that YOU wrote the stuff that follows that line, not me. In general, I would absolutely NOT want anyone to think I'd written anything you wrote! Guess I'm inclined to feel a bit of the second, and do some of the third.

The rest of what you wrote in the included messages isn't worth worrying about. It's taken badly out of context (surprise), and doesn't say anything new in any event.

Cheers,
Tom

By now, even you know that standing wave current phase is
fixed and unchanging and that those delay measurements of yours
are invalid whether made on a wire or on a coil.

> The loading coil isn't making the antenna act like a physically longer
> antenna.

Of course not! The loading coil is making the antenna act
like an electrically longer antenna by adding a phase
shift through the coil. The electrical lengthening is
what resonates the antenna feedpoint to a pure resistance.

> In the extreme case of a physically short inductor at the
> feedpoint, it's simply modifying the feedpoint impedance and has no
> effect whatever on the antenna's radiation.

Nobody has ever said it affected the antenna's radiation so
that has been and is still just a straw man.

> As the inductor gets longer,
> it does become some part of the antenna, but adding an inductor which
> resonates, say, a 45 degree physical radiator doesn't make the antenna
> act like a 90 degree physical radiator.

Of course not and nobody has ever said it does. It increases
the electrical length and brings the forward and reflected
waves into phase with each other. That's why the the feedpoint
impedance is resistive.

Those are traveling waves of *EM energy* where the power is indicated
at a point as the energy flows through that point. Assuming Z0=50 ohms,
the Bird indicates the number of joules per second flowing toward the
load when the slug is in the forward position. Turning the slug around
causes the Bird to indicate the number of joules per second flowing
toward the source.

The only way to have standing waves of EM energy in a transmission
line is to have two EM waves flowing in opposite directions. I have
asked you before to explain how standing waves develop without the
existence of a forward traveling wave and a rearward traveling wave.
Your silence on that subject has been conspicuous by its absence.
Do standing waves appear by magic?

Ian, I've not detected this particular disagreement about waves on
transmission lines in the group. I would be most grateful to see a brief
statement of where and how Bird's interpretation of theory is found infirm.

If correcting the power factor didn't cause a phase shift, the
power factor wouldn't change but we know it does. That phase
shift is exactly what we are talking about. The coil shifts
the phase of both the forward wave and reflected wave thus
furnishing some much needed electrical degrees in order to
resonate the antenna by bringing the phasor sum of the forward
and reflected voltages into phase with the phasor sum of the
forward and reflected currents.

Any power engineering textbook will tell you what happens to the
phase when the power factor is corrected. Hint: If the phase
stayed the same, as you assert, nothing would change. But we
know that correcting the power factor changes the phase. That's
exactly what correcting the power factor is all about.

> The truth is the loading inductor almost never has the same phase shift
> in current as the missing antenna area it replaces, and it almost never
> has the same "current drop".

The inductor does indeed
contribute a phase shift that is not zero. In a one wavelength
system, the coil can just as easily contribute a current RISE
as a current DROP. That fact alone is reason to drop the flawed
model. Current cannot be created in a coil by sucking it out of
earth ground which is what your theory have us believe. But of
course, you have refused to discuss the subject.

> I can have an antenna of given dimensions with a loading coil at one

Of course, but that is beside the point. Every real world inductor does
contribute its own unique phase shift and its own unique current change,
rise, fall, or equal at current nodes and antinodes. You have absolutely
refused to discuss that current rise. One wonders why.

> If I had a coil that was compact and not against the groundplane with

Resorting to a specially designed coil completely different from
anything used in the real world has been your specialty. If your
theory only works for only one special case and is not valid for
the general case, it's time to junk that theory.

After failing a dozen times to achieve equal current at both ends
of numerous coils, you finally declared victory using a small
toroidal coil. Uhhhh Tom, one out of twelve doesn't prove much.
I have shown you how to achieve equal current with any coil. It
just depends upon where the coil is placed in the standing wave
environment.

> A few people have violated the rules of charge conservation, charge
> movement, and misapplied the concept of standing waves, but the single
> largest error is standing behind the myth or misconception that that
> loading coil somehow acts like the "missing area of antenna".

The coil's function is to bring the forward and reflected waves
into phase so the feedpoint impedance will be purely resistive.
It cannot do that if it has no effect on phase. Your theory
is full of holes.

The coil affects the electrical length of the antenna, not the
physical length. Nobody has ever said it replaces the missing
physical length of the antenna. Your implication is that same
tired old straw man riding that same old dead horse.

Please stop trying to twist what we are saying and fix the
twist in your own misconceptions. For instance, how does your
theory handle a current rise through a coil as illustrated at:

http://www.qsl.net/w5dxp/test316.GIF

in the right hand part of the graphic. Why do you refuse to
discuss this current RISE?

Oooops, carefull here.
As far as I know, nobody has claimed that inserted loading coil replaces the

"missing" degrees of the radiator in terms of providing magical properties that would look like that "replaced" portion of the antenna, or make the antenna act like 90 degree full size physical radiator.
What we are saying that the loading coil appears to replace "missing" electrical degrees of the radiator in order to make it resonant, that is back to 90 electrical degrees (has to be in order to resonant), which rest of the existing "straight" radiator forces it to do (+/-). Radiation properties and efficiency of the loaded antenna is proportional to the area under the current curve. It is obvious to anyone comparing the area under the current curve of full size quarter wave radiator vs. loaded radiator that there is huge difference in area under the curve and performance, efficiency, which is known and been verified by numerous measurements.
HOW the current curve is modified by different loadings and position along the radiator is important in knowing how the current distribution curve along the radiator is modified.
The whole controversy is that "gurus" claim current doesn't drop across the coil, while we say that it does, therefore making the area under current curve above the coil smaller and effciency of loaded antenna worse than they believe and insist on.
Again, when applied in modeling programs, wrong assumption will produce erroneous results, which will be magnified in multielement antenna designs.
So the "gurus" basically ignore behavior of coil in the standing wave environment along the loaded radiator, where the current drops from max at base to zero at the tip, but coil would magicaly resist that, because, bla, bla, bla.... (see their "reasons")
So while everyone knows (?) that standing wave current drops acros (along) the wire (all the antenna books show that), but it is "impossible" to drop along the coiled wire (real inductance - coil, loading stub). Reality and measurments prove that, but according to them "it can't be so".

I am already gathering necessary hardware to do more experiments, measurements to show what is really happening, and will prepare articles how to model and apply it to antenna design.
I would challenge the "unbelievers" to join me and repeat the tests, to see wasaaaap.

W8JI says we are correcting the power factor. Every EE knows that
correcting the power factor involves shifting the phase, i.e.
the coil cannot correct the power factor without providing a phase
shift.

> The whole controversy is that "gurus" claim current doesn't drop across the
> coil, while we say that it does, ...

That context is specifically inductively loaded mobile antennas
where the current decreases from source to tip of the antenna,
true for all electrical 1/4WL monopoles.

For other antennas, the current may DROP, the current may RISE,
or the current may STAY THE SAME magnitude depending upon where
the coil is installed in the standing wave system. In particular,
none of the "gurus" has even attempted to explain the RISE IN
CURRENT through the coil in the right hand system at:

http://www.qsl.net/w5dxp/test316.GIF

There have been about 10 examples proving the "gurus" wrong and
they simply chose to ignore those examples. They complain that
those examples are biased toward technical correctness. I say,
YES, THEY ARE. AREN'T THEY SUPPOSED TO BE TECHNICALLY CORRECT?

916. Improving FM in building

Newsgroup: rec.radio.amateur.antenna
Date: 2006-04-12 15:28:23 UTC
From: amdx <amdx@worldnet.att.net>
Message-ID: <2bf27$443d1c89$45011502$10556@KNOLOGY.NET>
Source record: 61058

The health club I belong to has poor FM reception inside the building.
I'm trying to get them to improve it. The thought I have is to install
an outside omni antenna and connect it to an inside identical antenna
hanging down from the ceiling.
Is this a workable idea?
Does anyone have info to help make the improvements?

Thanks
Mike
PS---This is for all the personal FM radios worn by the exercisers.

The Bird 43 has only one scale calibration: power. Readings on that scale represent the power delivered to a 50-ohm load when the sensor is turned to the forward direction. However, the instrument internally senses only the voltage and current on the line. The "power" reading is only a calibration, and is only completely meaningful when you use the instrument in the same circumstances as when it was calibrated.

Now what happens if the load is not exactly 50 ohms? What happens when you turn the sensor around? You then get some new and different readings which have to be called "forward power" and "reflected power" - because "power" is the only thing the Bird's meter scale is calibrated to indicate.

The Bird Corporation's Application Note "Straight Talk About Directivity" discusses the meaning of "forward and reflected power" indications with a mismatched load. That document does not directly address your question, Chuck, but takes the subject to a further level of detail about the accuracy of the real-life instrument, and its limited ability to discriminate between forward and reflected waves.
http://www.bird-electronic.com/app_notes/StraightTalkAboutDirectivity.pdf

One notable thing about "Straight Talk" is how all the calculations begin by taking the square root of the power indications. In other words, all the relative RF power indications from the meter scale are

converted into relative RF voltages, and all the real calculations are done on the voltages.

Another interesting observation is that if you have a mismatched load, such that the meter indicates say 93W with the arrow on the sensor pointing forward and say 23W with the sensor rotated 180deg, then you would find that 70W is being delivered into the resistive part of the mismatched load impedance (assuming perfect directivity and no errors of any other kind).

There are two schools of thought about the physical meaning of all this.

One is that if the meter scale says "power", then there genuinely are forward and reflected traveling waves of power on the line. In the "93 - 23 = 70W" example, the belief is that there genuinely is a power flow of 93W towards the load, only 70W of which is accepted and 23W is returned.

The other school of thought is that that's not true. The meter may *read* more "forward power" than is actually being delivered to the load, but that is a false indication because the instrument is not being used in the situation for which the power scale was calibrated. Therefore it is not to be taken at face value - and above all, the letter "W" on the meter scale does not prove the physical existence of forward and reflected waves of power.

Every detail about a Bird 43 or similar "directional wattmeter" can be explained quite simply in terms of travelling waves of voltage and current. And I do mean every detail - including why a meter that happens to have been calibrated in "power" will read as it does.

The classic explanation was by Warren Bruene, W5OLY, of the Collins company. He invented the familiar "Bruene bridge" directional coupler which samples current through a toroidal transformer, and voltage by a voltage divider. The principle of the Bird 43 is the same, but the two separate sampling functions are easier to see in the Bruene bridge.

After a previous incarnation of this debate in 2002, I wrote a 2-page article which summarised Bruene's original article (from QST, April 1959) and explained the crossover to the Bird sampling technique: http://www.ifwtech.co.uk/g3sek/in-prac/best-of.htm#bruene

An equally good explanation of those same meter readings can be constructed by regarding the Bruene "bridge" literally as an impedance bridge. There is no inconsistency between the two approaches - they are just two different viewpoints looking at the same reality.

On the other hand, we have yet to see an explanation in equivalent physical detail that is based entirely and exclusively on the viewpoint of travelling waves of power (with no borrowing from explanations based on voltage and current).

I am not blaming the Bird Corporation for any of these misunderstandings. They are simply telling users how to work with the

available "power" markings on the meter scale. The problem is when some users take them too literally.

Ian White, GM3SEK wrote:
"---it`s about the theory about standing waves and traveling waves."

Bird is congruent with Terman. Both have been around for a long time and the theory works.

Reverse engineer the Bird. The critical step is adjusting the two samples for equality so that the 180-degree phase shift reflection causes produces cancellation in one direction of pickup so that the samples from the other direction can be measured.

It might work OK, especially if the building is really sealed tight to RF.

You may want to add a cheap FM preamp with the outside antenna connected to the input and the inside antenna connected to the output, so that the connection between the antennas has a tad of gain, rather than just loss.

Hi Ian,

This argument sets up the first school for failure that is already
admitted to. Your statement from the second school that:
>*read* more "forward power" than is actually being delivered to the
>load, but that is a false indication
is already admitted to explicitly from the first school:
>93W towards the load, only 70W of which is accepted and 23W is returned.
in that the 70W NOT 93W is the correct indication.

The "second" school has nothing to offer on the subject. The
"because" that attends their "discovery" of this error is specious
logic.

The fact remains that when you subtract 23W from the 93W you do find
70W in the load. The second school would have us believe none of the
numbers correlate to power, and yet the results bear out just the
opposite every day.

The second school needs to stay after class.

Power factor correction shifts the relative phase of current with respect to voltage. When talking about a phase shift, you have to be careful to say what is being shifted relative to what else. There are lots of possibilities.

A series inductor (a non real, ideal one) with absolutely no phase shift or magnitude change in the current from one end to the other, still produces a phase shift of input voltage to output voltage, so the relative phase of voltage to current at the input is different compared to the relative phase of voltage to current at the output. I think this is the power factor correction effect W8JI is referring to.

Any real inductor does this, and also does some other things.

One correction. The Bird wattmeter is installed at a point
on the transmission line and it measures the power at that
point. What is traveling is the energy. Power is the number
of joules per second passing a fixed point. "Power flow" is
somewhat of a misnomer.

> The other school of thought is that that's not true. The meter may
> *read* more "forward power" than is actually being delivered to the

It certainly is being used in the situation for which it was
calibrated if the Z0 of the transmission line is 50 ohms.

> On the other hand, we have yet to see an explanation in equivalent
> physical detail that is based entirely and exclusively on the viewpoint
> of travelling waves of power ...

Please give up on your misconception. Those are traveling waves
of *ENERGY*. Power is what is measured when traveling energy passes
a fixed point. Perhaps that is your whole point of confusion.

Cecil, W5DXP wrote:
"Any power engineering handbook will tell you what happens to the phase when the power factor is corrected."

Most industrial loads have a lagging power factor. They represent an inductive reactance in addition to their resistive loads. Extra energy must be generated and transmitted just to charge this inductance which does no work but demands current. Extra loss comes from this reactive load. This is eliminated by tuning the inductance out with a capacitive reactance at the load. This is often an overexcited synchronous motor. When the motor has no mechanical load it is often called a "synchronous capacitor".

An antenna needs zero reactance too if it is to accept maximum energy and not make standing waves. Reactance impedes energy to the antenna. Reactive current also increases loss in the transmission line as it does in the case of the power utility frequency. So j0 is a goal in many instances.

Best regards, Richard Harrison, KB5WZI

Yet W8JI would have us believe that power factor correcting capacitor functions faster than the speed of light, making an instantaneous phase correction. Sorry, the real world doesn't work that way.

The bottom line is that we cannot shift phase without delaying something, either voltage or current. Contrary to the presuppositions of the lumped-circuit model, neither voltage nor current can travel faster than the speed of light. That means that any phase shifting of the relative phase angle difference down to zero results in a delay.

I have seen it explained as "apparently" traveling faster than light. That's just one more patch on an already flawed mode.

If the voltage is leading the current, and the current
experiences no phase shift through the coil, doesn't that
imply that the voltage must travel faster than light and
indeed jump forward in time to catch up with the phase
of the current?

What does it mean to the E-fields and H-fields to say
the voltage is leading the current?

If you consider a request for you to honor the netnews
guidelines for attributions a problem, then it's your
problem, not mine. No ethical person would attribute one
person's postings to someone else.

If you don't like that attitude, I suggest you cease and
desist from violating the netnews guidelines for attributions.
I'm going to point it out every time you attribute a posting
from someone else to me or when you attribute one of my
postings to someone else.

When trimming one line attributes the posting to a completely
different person, that is a clear violation.

Agreed, it's not quite stated as such. Here are some statements which were made:

From your web page http://www.k3bu.us/loadingcoils.htm, in bold type:

"In summary:
The current in a typical loading coil in the shortened antennas drops across the coil roughly corresponding to the segment of the radiator it replaces."

By Cecil, on March 5, on this newsgroup:

"A loading coil thread is climaxing over on qrz.com. I have used EZNEC to generate a graphic which shows a 3/4WL vertical and a similar 1/2WL vertical with a ~1/4WL loading coil. The loading coil is a wire helical coil containing (surprise) roughly 1/4WL of wire. The coil does a good (not perfect) job of replacing 1/4WL of wire. Many things can be gathered from observation of the current reported by EZNEC for the two antennas. The coil occupies roughly the same number of degrees of the antenna as the wire it replaces. The current at the top and bottom of the coil is roughly the same as the current at the two ends of the wire it replaces. Is the coil an exact replacement? Of course not."

> What we are saying that the loading coil appears to replace "missing"
> electrical degrees of the radiator in order to make it resonant, that is
> back to 90 electrical degrees (has to be in order to resonant), which rest
> of the existing "straight" radiator forces it to do (+/-).

It's getting muddier and muddier just what you mean by "replace". Nobody has questioned that a loading coil makes the antenna resonant; that's its purpose. But that's simply an impedance transformation property which can be accomplished well away from the antenna by many different methods.

> Radiation
> properties and efficiency of the loaded antenna is proportional to the area

I agree with all this. I'm glad you've clarified this for the benefit of
posters like the one to whom my recent posting was directed.

> The whole controversy is that "gurus" claim current doesn't drop across the
> coil, while we say that it does, therefore making the area under current
> curve above the coil smaller and effciency of loaded antenna worse than they
> believe and insist on.

I don't think you'll have any trouble winning your arguments against
your imaginary "gurus", whomever and whatever they might be. Over two
years ago I made careful measurements which showed a current difference
between the top and bottom of a loading coil. Cecil posted an EZNEC
model on his web site showing a substantial difference. I've commented
on it several times, explaining the reason for the difference, and
modifying the model to illustrate the explanation.

The controversy is in the explanation of the difference. It simply
doesn't require Cecil's theories. I've never been able to tell exactly
what your theory is, if you indeed have one.

> Again, when applied in modeling programs, wrong assumption will produce

Would you name these "gurus" so we can read their postings and see what
you're talking about?

> So while everyone knows (?) that standing wave current drops acros (along)

> I would challenge the "unbelievers" to join me and repeat the tests, to see
> wasaaaap.

You'll be surprised when everyone agrees that there's a current
difference between the top and bottom of the coil. Unless your "gurus"
show up, whomever they are.

I've already made a test and posted the results, over a year ago. When it failed to show a current difference anywhere near the number of degrees it "replaced", your complaint was that I was using an inductor which was too small physically. So obviously your theory works only on certain size inductors. Once you or Cecil has the theory fully worked out, it should be able to not only tell us what the current difference between top and bottom should be, but also how physically large an inductor must be before the theory works. And why it doesn't work for physically small inductors.

Those of us stuck with old fashioned conventional theory can explain the drop for small as well as large coils, so you folks have a bit of catching up to do.

I think a lot of the experimental work can be done by modeling. I'd be interested in hearing of any cases where measured results differ significantly from EZNEC results. Incidentally, your web page is a bit outdated in that respect, apparently being written before EZNEC v. 4.0 was available with its automated helix creation feature.

Roy, maybe you need to learn the definition of "roughly".
It is certainly not "exactly" as you are clutching at straws
to imply. Why you need to change the definitions of words
is obvious from your flawed arguments. Exactly what is
it about "roughly" that you don't understand?

> It's getting muddier and muddier just what you mean by "replace".

That meaning has never been in doubt. "Replace" has always
meant bringing the necessary signals back into phase so the
feedpoint impedance is purely resistive. You know perfectly
well that it has never been about physical length or radiation.
Those are just another two of your straw men. Your attempt
to muddy those waters has been going on for years including
your attempt to discredit the distributed network model in
favor of the lumped circuit model. Hint: The distributed
network model is a superset of the lumped circuit model.
If you succeed in discrediting the distributed network
model, you have automatically succeeded in discrediting
the lumped circuit model. It's a lose-lose proposition
for you.

If they have cable TV in the club you can put a set of rabbit ears
in one of the outlets and see if that helps. A preamp may help too.

Cecil,

Is 10 degrees of phase shift "roughly" equal to 75 degrees of phase shift? I don't think anyone is trying to nit-pick the numbers to a precision of several significant figures. A multiple of greater than 7 would seem to be just a bit outside the scope of "roughly".

Source record: 60990

I don't know that I buy your statement that ground losses aren't extremely important for receiving applications. Antenna systems are bi-directional. If you lose xdB of transmitted sigal due to ground losses, then you are also going to lose xdB of received signal due to ground losses.

A more important issue is that ground losses are very important when receiving a lightning strike. It may be effective to bury several runs of bare #6 copper in trenches radiating from your "ground point". The QTH here is located on a solid rock slab. All grounding is through buried #6 wires and a few ground rods driven laterally between the rock layers up by the tower base.

Of course not. The 10 degrees of phase shift has already been
proven to be wrong because of reflections within the coil.
Why do you insist on bringing up old invalid data?

Please note that *nobody* is alleging that the phase shift
through a 75m bugcatcher coil is 75 degrees. That is just
another one of your straw men.

Now why don't you become a rational, ethical person and
suggest a valid way of measuring the phase shift through
a coil? Can you improve on my suggestion of yesterday?

>calibrated if the Z0 of the transmission line is 50 ohms.
>
I'm not sure which "transmission line" you meant here, but I don't think
it matters anyway.

The inserts are individually calibrated with a 50 ohm load impedance
connected to the "Antenna" socket. The internal pot is adjusted to give
the correct power reading (at one point on a meter scale that is
pre-printed), and then the insert is reversed and a tab is bent to
adjust the capacitive coupling to give the lowest possible reading.
There may be some interaction requiring the two adjustments to be
repeated, I don't know.

If you meant the transmission line outside of the instrument, the
calibration load may or may not include a length of matched 50 ohm
transmission line - it doesn't matter. Inside the instrument, the

characteristic impedance of the internal line is 50 ohms in order to avoid introducing an impedance bump into a system that is already matched, but even with say a 57 ohm internal line, the Bird insert could be set up to indicate power correctly into a 50 ohm load. The only difference is that the performance would become frequency-sensitive.

>> On the other hand, we have yet to see an explanation in equivalent

>
>Please give up on your misconception. Those are traveling waves
>of *ENERGY*. Power is what is measured when traveling energy passes
>a fixed point. Perhaps that is your whole point of confusion.

You're right, they would indeed be travelling waves of energy rather than power. But otherwise the same challenge is still out there: if forward and reflected travelling waves of energy exist, we would expect to see a detailed explanation of how the Bird or any similar instrument interacts with such waves <as distinct from> the explanations that we already have for travelling waves of voltage and current.

I do not expect equal currents at the top and bottom of any real-life coil. That is a strawman argument, based on what *you* claim other people are saying.

But you can make coils that come quite close to behaving like an ideal lumped inductance. And the closer they are, the closer to equal I expect the currents at the two ends to become, and the closer to zero I expect the phase shift in current to be... because that is how pure inductance behaves, with no exceptions due to "special situations".

Cecil, in all sincerity, have a good trip and please drive safely. I'd have been much safer on the roads last weekend if I hadn't been thinking about this stuff as well.

Cecil,

I will retain the entire message below, so that I am not accused of misattribution.

Where did you get this idea that the velocity factor is constant? Specifically, why is the velocity factor of a resonant coil the same as the velocity factor of a significantly shorter coil? It is pretty well accepted that the inductance of coils does not scale linearly with the length of the coil. Therefore any arguments about based on direct calculation of Vf from L and C would seem to fail to support your model.

I can think of two possibilities.

The first is that you treat this entire problem as a transmission line. Most people would accept that the velocity factor for 200 feet of RG8 is indeed the same as the velocity factor for 100 feet of the same cable.

However, the velocity factor appears to be the crux of your latest argument about the behavior of a loading coil. It is not exactly acceptable technique to include the desired answer as part of the proof.

The other possibility is that you are taking the lead from one of the Corum papers. In particular, I am referring to the paper labeled:

"TELSIKS 2001, University of Nis, Yugoslavia (September 19-21, 2001) and MICROWAVE REVIEW"

If so, I suggest you go back and reread what was written. He specifically says (page 4, left column) that the equations for velocity factor that show Vf as a function of diameter, spacing, and wavelength apply only at resonance. The exact words are:

" . . . an approximation for M has been determined by Kandoian and Sichak which is appropriate **for quarter-wave resonance** and is valid for helices . . ."

The emphasis on quarter-wave resonance was in the original; I did not change a thing. The remainder of the paper clearly indicates that he is talking about coils near or at resonance. There is no extension of the Vf equations to short non-resonant coils. Indeed, he comments several times that his model smoothly joins with the lumped circuit model for smaller coils. That would require a non-constant Vf.

You attempt at decomposition of a resonant coil into smaller subcomponents simply fails.

This is not an "ignorant diversion". If you have a third method of
supporting your claim of constant Vf, let's hear it.

73,
Gene
W4SZ

It means that the current at both ends of the coil was delayed
(relative to its phase if the coil had not been there). It means that
there was a voltage difference across the ends of the coil that drove
that current through the coil.

Cecil,

You spent a lot of time developing the "10 degree" model for the bugcatcher coil. When and how did it get proven wrong? The only thing I can recall is that you said it did not make sense technically, and therefore it must be wrong. Recently you launched into this business about adding turns to make the coil resonant. As I just explained, I believe that approach is total nonsense.

You keep referring everyone to the now famous gif image on your web page. The question becomes why is EZNEC correct in supporting your position at some times and incorrect when it does not support your position at other times?

Sincerely, Ian, how do you explain one amp on the source side of
a coil and two amps on the whip side of a coil? Nothing in your
response even came close to answering that question.

If you are dedicated to technical correctness, your evasion
of this technically simple question is perplexing.

How is it possible to have one amp "flowing into" the bottom
of a coil and two amps "flowing out" of the top of the coil?
If you really believe that one amp is flowing from the earth
ground to the coil through displacement current, please just
say so.

> losses, then you are also going to lose xdB of received signal due to
> ground losses.

Your statement about the "bi-directionality" (usually called reciprocity) of antennas is true. But what counts when receiving is the signal to noise ratio. If you lose x dB at the transmitter, the person receiving the signal gets a signal that's now x dB lower than it was before, and the noise is the same. So the S/N ratio has been reduced by x dB. Therefore it's desirable to minimize loss at the transmitter antenna.

But what happens when the receive antenna has x dB loss? At HF, the dominant source of noise is atmospheric (and QRM). Adding x dB loss at the receive antenna reduces both the signal *and* the noise by x dB. The result is the same S/N ratio as before. That's why efficiency isn't important for HF receiving antennas. Of course, you could reach a point where the efficiency is so bad that the receiver noise dominates. Beyond that point, lowering receive antenna efficiency will reduce S/N ratio. But this point is usually a long way down. Likewise, at VHF and above, where atmospheric noise is low and receiver noise dominates, high receive antenna efficiency is desirable. But the original question was, I believe, in reference to HF receiving.

> between the rock layers up by the tower base.

Lightning protection and mains safety grounding are separate issues with somewhat different requirements. Although a good lightning ground probably usually constitutes a reasonably efficient RF ground, that's not always the case, and the reverse isn't necessarily true either.

Gene, to the best of my knowledge, you have never
misattributed anything.

> Where did you get this idea that the velocity factor is constant?

The equation for velocity factor includes coil diameter,
turns per inch, and wavelength. Keeping the coil diameter
constant, the turns per inch constant, and the wavelength
constant should ensure that the velocity factor is constant.

> Specifically, why is the velocity factor of a resonant coil the same as
> the velocity factor of a significantly shorter coil? It is pretty well
> accepted that the inductance of coils does not scale linearly with the
> length of the coil. Therefore any arguments about based on direct
> calculation of Vf from L and C would seem to fail to support your model.

You are obviously mistaken. If you increase the L by lengthening
the coil, you have also increased the C by the same percentage.
The L and C for any unit length are the same no matter how long
the coil or transmission line is.

> " . . . an approximation for M has been determined by Kandoian and
> Sichak which is appropriate **for quarter-wave resonance** and is valid
> for helices . . ."

Yes, but if one doesn't change the frequency or the diameter or
the turns per inch, the approximation should hold since nothing
in the VF equation changes by shortening the coil. One should be
able to shorten or lengthen the coil andmaintain the same VF.

Seems it is up to you to prove what you are saying. Please prove
that the ratio of L to C ratio of a coil changes with length. That
should be an interesting proof.

In order to avoid any delay through the coil, you propose a delay
in the one inch of wire at the bottom of the coil? Does that really
make sense to you? How is this magic delay accomplished?

Yes, it was a waste of time since I didn't accomplish the
goal of eliminating reflections. The phase angle between
the source voltage and source current is 71 degrees. That
proves that I failed to eliminate reflections.

> You keep referring everyone to the now famous gif image on your web

EZNEC doesn't differentiate between standing waves and traveling
waves. The user has to ensure there are no reflected waves. I
failed in that task. It's no big deal. I fail quite often.

My position is technical facts and accuracy. What is your
position?

Of course, in the context of a balloon, it's important to remember
that atomic hydrogen is not generally found -- instead, you see H-H or
H2 molecules, so hydrogen gas is approximately 1/2 as dense as helium,
not 1/4 as dense. (Of course, others have already mentioned this.)

| Number of Protons/Electrons: 1
| Number of Neutrons: 0
|
| hydrogen is also known to have *at least* 5 known isotopes (all unstable and
| all prone to radioactive decay).

Well, the most common isotope of hydrogen, which is just a proton with
no neutrons (and is called protium when you need a name), is NOT prone
to radioactive decay. Neither is deuterium, for that matter.

According to http://en.wikipedia.org/wiki/Isotopes_of_hydrogen, seven
isotopes of hydrogen have been found, but the first two, protium and
deuterium are stable, the third, tritium is unstable but not extremely
so (half life = 12 years.) The rest are extremely unstable and not
naturally occurring in any signifigant degree if at all.

Though I'm not sure what any of this has to do with a balloon or blimp
-- protium is 6500 times more common than deuterium, and tritium is
much much less common than that. Just assume your balloon has normal
hydrogen in it.

I wonder how the local CCR would react to me putting up a large HF
antenna with a balloon ... poorly, I imagine :)

Exactly the way it is accomplished if you apply AC to an LC "L" low pass filter that droves a resistor load. The short antenna acts as the capacitor (in parallel with losses and radiation) in the circuit. It is resonated with the series inductor so both the inductance and capacitance cancel, so the source drives only the losses and radiation. Power factor corrected.

If you don't believe me, simulate it with EZNEC. Connect a source to a parallel combination of C and R. Record the phase of the current with respect to the voltage (the current will lead). Then add a series inductance that cancels the capacitance, and the current will be delayed till it matches the phase of the applied voltage. Power factor corrected.

Heaven only knows why Cecil keeps insisting on bring up "lumped circuit theory" when it's clear that nobody else here is considering it, but since he does and keeps insisting that we provide an example of a lumped circuit that has behaviour which mimics the behaviour of some distributed circuit:

--100 ohm resistance to common
--100uH inductance in series with that resistance
--25.856pF capacitance from the other end of the inductance to common
--Feed power across the capacitance
--Frequency = 3.97887MHz (The inductance is +j2500, if you wondered why)
--Adjust the power source so its output current is 1.30 amps RMS.
--Note the current in the resistance is then 2.10 amps RMS.

There's a whole continuum of component values, and a virtually infinite set of circuit topologies, that yield the same terminal performance W.R.T. currents. But who besides Cecil cares? It has nothing to do with the issues at hand, and it's not very interesting.

Cheers,
Tom

This is another area where you fall right square on your face.

An inductance changes the relationship between phase of voltage and
current, NOT current through the inductance from terminal to terminal.

You either know that and are intentionally avoiding it to save face, or
you need to brush up on basic theory.

> > The whole controversy is that "gurus" claim current doesn't drop across the
> > coil, while we say that it does, ...

Yuri again distorts fact. What everyone is saying is there can be a
current change, but it is not caused by standing waves or missing
antenna area. It is caused by displacement current, and so can have a
wide range of change in a given antenna.

Please write that down Yuri, and keep it in front of you so you don't
forget again!

Yeah, that's likely to cause problems. The rabbit ears will "leak"
signals that the cable company has no right to be broadcasting... some
of the cable channels overlap with air-traffic control frequencies,
amateur radio, and so forth.

Complaints are likely to arise, either because the egress leakage from
the cable through the rabbit ears interferes with licensed radio
services, or because a licensed transmitter somewhere in the area of
the club leaks back into the cable and wipes out TV reception for
other cable customers.

Upon locating the source of the problem, the cable company *might* be
polite enough to simply insist on disconnecting and terminating the
cable outlet in question. Or (depending on how irritated their Cable
Guy is that day) they might just cut off the cable service to the club
entirely.

Roy,
the above are the attempts to illustrate and add some more to understanding and reasoning why the current across (alonng) the loading coil, roughly half way or 2/3 up the resonant quarter wave radiator is larger at the bottom and drops about 40 - 60% at the top. While one side argues that it is (almost) the same, we argue that it drops. That is the argument and not detours to degrees, phasors, and rest of the mud that was rehashed here.

If I remember correctly you inserted the coil at the base and I am not sure if it was resonant quarter wave radiator. Can you describe the setup, length and frequencies used? You should try to use quarter wave resonant radiator with coil about 1/2 to 2/3 up the mast and tell us what the current values are. W9UCW has pictures and data measured, we should try to emulate this situation, that is the object of controversy. Cecil mentioned cases when current can be the same, or lower at the top, or bottom, depending where the same coil is placed in relation to the standing wave and current distribution on the radiator. Are you denying that this is the case or something wrong with W9UCW test setup and results?

> The controversy is in the explanation of the difference. It simply doesn't
> require Cecil's theories. I've never been able to tell exactly what your
> theory is, if you indeed have one.
>

The controversy is about the claims that the current at the ends of the typical loading coil is the same or different in range of 40 -60% drop. Its not my theory, it is the reality that we are trying to bring forth and correct misconceptions that are obviously floating around since 1953. My approximation and explanation (latest) I mentioned is in one of my posts in reply to W8JI "arguments" (to do with impedances).

>> Again, when applied in modeling programs, wrong assumption will produce

>
I have not verified it, but W9UCW claims using ferite inductor and got very similar results. I believe your test, you used coil near the base. I will run test with different inductors from bugcatcher type, "no good" Hustler, to ferite and in different positions.

> Those of us stuck with old fashioned conventional theory can explain the
> drop for small as well as large coils, so you folks have a bit of catching

> up to do.
>
Looks like the size of the coil has small effect on current variation (unless high resistance). Position of the coil in relation to current distribution along the radiator would cause equal (special case), less on the top of coil or more, depending where on the standing wave curve coils is located. In our case we are arguing about 2/3 up the resonant radiator.

> I think a lot of the experimental work can be done by modeling. I'd be
> interested in hearing of any cases where measured results differ
> significantly from EZNEC results. Incidentally, your web page is a bit
> outdated in that respect, apparently being written before EZNEC v. 4.0 was
> available with its automated helix creation feature.
>
Now with solenoid generation in EZNEC 4.0 it helps to get away from the lumped inductance and it shows that there is current drop, reflecting situations in question. Also the loading stub produces similar results. Cecil showed the cases and with different positions along the current curve, demonstrated in EZNEC huge differences in current at the ends of the coil. But this is getting strangely ignored and instead we get all kinds of "reasons" why it can't be.
I am sorry I dropped out of this due to AOL dropping NG, and I thought that reality would be understood by now. Only when Cecil told me that subject flared up again and nothing changed, I rejoined the discussions. I think really at this point, it is beating the dead horse. I will do the tests and write it up. I will try to corellate the tests with modeling in EZNEC. If someone denies the reality, that's their choice. I will post the progress on my web page.
I can't stomach W8JI "exchanges" any more. No answer to questions or following the points, just twist and jive.

> Roy Lewallen, W7EL

I didn't look it up, but is there way in EZNEC to know or calculate the inductance of modeled solenoid? Or better, specify the inductance and let the EZNEC "make" the coil of prescribed diameter and TPI?

This works for GPS. I had a project at China Lake Naval Weapons Center a
few yeards ago, where they pumped GPS through an amp and rebroadcast it in
the lab where they were evaluating a missile guidance syatem.

(It doesn't matter how sure I was that there was no fuel and no warhead in
the missile; I did NOT like walking in front of that thing.)

The "current will be delayed"? That cannot be, according to
W8JI and W7EL. They say there is no more delay through a 6"
coil than through a 6" wire. That's what the argument is all
about. Instead of the current being delayed, their voltage
jumps ahead in time at greater than the speed of light in
order to correct that power factor.

You are talking about delay from one end of the coil to the other. I
am talking about delay, compared to the same circuit without the
inductor in place. See the difference?

You still haven't told us who this "side" is that argues that the
current is the same at the bottom and top. I assume it's those unnamed
"gurus" who you haven't identified. It shouldn't be a problem to show
that the other "side" is wrong if it doesn't exist.

You can find my earlier postings at groups.google.com. The results
you're asking about were posted on Nov. 11, 2003. You can find your own
comments about my measurements there also, on the same date.

I'm sorry, but I don't have time to try and model or carefully analyze
W9UCW's results. The results for a toroid show more current difference
than I'd expect, and suspect that's due to the shunt capacitance of the
physically large meters he was using.

Before, you complained because the coil wasn't physically long enough.
Now you want it placed somewhere else along the radiator. Sorry, after
the reaction I got to my previous test, I have no interest at all in
making additional ones.

The only posting I see that fits that description is your posting on this thread on April 7. As I read it, you say that as you put a coil higher and higher in an antenna, the inductance required to maintain resonance increases, and the difference in current between the bottom and top of the coil increases as the coil is made larger. I don't see any values or way of calculating them, but don't have any disagreement with the qualitative statements you made there.

I take that as a "no", you can't name the "gurus". The advantage of arguing against imaginary "gurus" is that you can have them claim anything you want. It shouldn't have taken you so many postings to prove them wrong.

Then you and Cecil have quite different theories, it seems. His doesn't predict the drop I measured. Those of us who are tired of the endless arguments should sit back and let you and Cecil go at it until you come to an agreement.

I don't know who "we" is. The technical theory I subscribe to doesn't require any particular placement of the coil.

I replaced the whip in one of Cecil's models with a lumped RC and got
the same result. Then I eliminated the ground and reduced the current
drop to near zero. I've commented on that on several occasions. That
certainly doesn't constitute "strangely ignoring" Cecil's model.

> I am sorry I dropped out of this due to AOL dropping NG, and I thought that

Let us know when it's available. Hopefully it'll actually happen this
time. Again, I'll be interested in knowing of any significant difference
between modeling and measurement results.

> I can't stomach W8JI "exchanges" any more. No answer to questions or

The answer to your second question is no. To your first, yes. What I've
done is model the inductor in free space with ends extended to the helix
axis (an option when creating it). Put a wire end-to-end down the center
of the coil with a source in the middle. Src Data will show you the
reactance, from which you can get the inductance. This seems to work
reasonably well provided that the frequency is low enough that the coil
is well below self resonance and low enough that it doesn't radiate much
but high enough that NEC-2 doesn't have trouble with the loop size. If
it shows good results in the Average Gain test, it's probably ok.

Would the inductor then be best right past the feedpoint? Certainly
having the inductor at the far end, or in the middle seems like a bad
place for it. (not talking about trap antennas)

> As the inductor gets longer,

Then there is your answer to who is "gurus" and who is "we".
"Gurus" know that current in loading coil is the same.
"We" know, measured it properly and argue that that is significantly
different.
I am sorry, you are wrong. I tried to follow some stepts to get to the
point, Tom ignores my points and jumps to lecture how, bla, bla...

I am really done here, you guys can believe what you want. Just that reality
doesn't jive with your "can't be".

> Any idea why that would be?

The amount the magnitude of the current drops across an inductor is determined primarily by the amount of inductance and the capacitance from the inductor to ground or the other half of the antenna. This is easily explained by simple lumped constant circuit theory. There's also some variation due to radiation and imperfect coupling between turns. In the extreme case of a very loose helix, coupling is poor and radiation is high, so the helix acts more like a wire than an inductance. This requires a more complex analysis, but that's also in the realm of well known phenomena. With this wide variation in physical possibilities, different results can't be avoided. What some of us have tried to do is explain why the results occur.

I don't know of differing results from the same physical setup, but it could surely happen. Making good measurements isn't a trivial task.

> Do you remember the name of the thread?

Current in antenna loading coils controversy (long). I made two sets of measurements. The second was posted on Nov. 11, 2003 and the first a few days earlier.

>> The loading coil isn't making the antenna act like a physically longer
>> antenna. In the extreme case of a physically short inductor at the
>> feedpoint, it's simply modifying the feedpoint impedance and has no
>> effect whatever on the antenna's radiation.
>
> Would the inductor then be best right past the feedpoint? Certainly
> having the inductor at the far end, or in the middle seems like a bad
> place for it. (not talking about trap antennas)

Generally not, but it depends on several factors. Moving the coil upward increases the radiation resistance of the system, which improves efficiency in the presence of ground loss. However, it also requires a larger coil, so the coil's resistance is greater. But the current at the location of the coil is lower, so overall I^R loss of the coil is often less with the coil somewhere around halfway up. The relative amount of

coil and ground loss, as well as the amount of top loading if any, are all factors in determining which position is best. This is really a separate question, and I don't have varied enough experience with HF mobile setups to be anywhere near an expert. Tom, W8JI, is though. You can take what he says on the subject to the bank.

In the graphic at: http://www.qsl.net/w5dxp/test316.GIF
in the right hand configuration the current at the bottom
of the coil is 1.3 amps and the current at the top of the
coil is 2.1 amps.

Your explaination for more current at the top of the coil
than at the bottom is that 0.8 amps of displacement current
is jumping up from earth ground into the side of the coil
and flowing out the top?

Would you please describe that bit of magic in a little more
detail?

You have completely ignored the EZNEC results posted at:
http://www.qsl.net/test316.GIF where the current at the top
of the coil is greater than the current at the bottom of the
coil. How would your theory handle a current RISE through a
coil?

Here's a graphic that might help: http://www.qsl.net/w5dxp/1WLDIP.GIF

The coil can have a current DROP, a current RISE, or equal currents
depending upon where it is placed in the standing wave system.

Most of the discussion has been about base-loaded mobile antennas.

Everyone have a nice Easter. I'll be away from my computer until
Monday.

Cecil,

I gave you a very specific reference to demonstrate your supposition was incorrect. You came back with nothing but, "Because I say so." You have not offered one shred of backing for your constant Vf argument.

And it is up to ME to further prove something?

I don't think so.

988. New program. COAX_VLF

Newsgroup: rec.radio.amateur.antenna
Date: 2006-04-13 04:40:32 UTC
From: Reg Edwards <g4fgq.regp@ZZZbtinternet.com>
Message-ID: <YaGdnZBrj84JS6DZRVnyvQ@bt.com>
Source record: 60930

Now available: Program COAX_VLF

The behaviour of transmission lines at the lower frequencies is more
complex than it is at HF and above. The effects set in sooner at
higher frequencies on low impedance coaxial transmission lines. They
are affected more at higher frequencies than other types of line.

As frequency is reduced below several hundred KHz the impedance Zo
increases, its impedance angle becomes more negative, and the
propagation velocity decreases. Unusual things happen such as
reflection coefficients being greater than unity and the SWR being
greater at the input end of a line than it is at the load end.

At power and audio frequencies Zo can be an order of magnitude greater
than the nominal HF value, and the angle of Zo aproaches -45 degrees.

It is useful to be aware of the magnitude of such effects. With coax
they can be experienced in small ways at frequencies as high as 2 MHz
or more.

Download program COAX_VLF in a few seconds from website below and run
immediately. Filesize = 48 Kilo-bytes. It is both practical and
educational. Try to fathom out how reflection coefficients greater
than unity can arise.

Yes, some time earlier today than that exchange, I posted elsewhere in this thread a specific circuit, complete with values, how the same thing is easily accomplished with the infamous ideal lumped components. No standing waves need apply. But of course if one used distributed reactances, one could easily get the same effect, and the analysis can easily be done w/o any reference to standing or travelling waves.

Cheers,
Tom

> idea why that would be?

Yes, because the physical construction of the coil and the antenna changes the capacitance from the inductor to the outside world and the impedance loading the coil. It is the ratio of capaciatnce of the coil to the outside world to the load impedance presented by the whip above the coil that causes or allows any phase difference in current or current level at each end of the coil.

It isn't standing waves, it is missing electrical degrees.

I can take a resonant mobile antenna of basically the same height and construction, change only the coil while maintaining resonance, and have difference of current and phase of current change all over the place.

Try reading:

http://www.w8ji.com/mobile_and_loaded_antenna.htm

there is a link to actual measurements in that text.

No. The current in the antenna below the loading coil (or a top hat of sufficent capacitance)is essentially uniform. This increases radiation resistance. Increased radiation resistance can increase efficiency.

See:

http://www.w8ji.com/radiation_resistance.htm

Hi Bob:

I have no experience with that brand, but I've used UV resistant (black tie warps) for years.
The feedlines on my tower are held up with them and I've noticed no degradation in them for the last 4 years. For what its worth, in the past I've used Scotch #33 black electrical tape and it has held hard-line and coax to my tower for 5 to 6 years with no problem. Some professionals I know use electrical tape for all but the largest runs of hard-line.

I actually had the chance to use one of these at a Titan II missile site
in Wichita, KS. when I was in the USAF back in the 80's.
I had been dispatched out to the base to do some maintenance on the VHF/UHF
radio equipment they used, and our departure was delayed for awhile due to a
snow storm.
I asked the site commander if I could use the HF gear to make a few
amateur radio contacts and he gave me permission. WOW what good signal
reports!
I was running the full legal limit on 75 and 40 meters through it and
whatever I could hear I could work. I made about a dozen contacts and the
commander must have gotten a little worried and ordered me to stop.
I guess I was lucky he let me make any contacts at all considering the
situation. Nice memory:-)
Anyway, the antenna was HUGE to say the least! it was made of cable for
the skirt and large tubing for the hat radials. I would guess about
100-150'+ across the bottom of the skirt. I haven't thought about that in
years. Thanks for reminding me of those times:-) Loved being in the Air
Force!

Aluminum works fine as a counterpoise.

However, The magnetic feature of the mag mount would most likely be inoperative. Magnets don't like Aluminum!!

Hi Yuri,

Yesterday I posted in this thread a very simple ideal lumped-circuit specific example of how it happens. Have a look for that. Consider the capacitance in that lumped circuit to be part and parcel of the coil in the distributed case, so you can't in the distributed case separate its current from the coil current; all you see is the current going in the "input" terminal (1.3 amps, per Cec's request) and the current coming out the "output" terminal (2.1 amps) into a load impedance. If you don't overconstrain the problem (that is, if you don't specify anything beyond reasonable input and output currents and load impedance) I can show you a lumped circuit with only series inductance, series resistance to represent loss if you wish, and shunt capacitance, that will do the same thing with respect to terminal currents.

It really is not a stretch at all to get more current coming out than going in. It WOULD be a stretch to have more power dissipated in the load than you put in the network, but that's not what's happening, of course.

Is that all specific enough for you, or would you like to give me a challenge with a different set of input and output currents and load impedance (which agrees with what you might actually observe in an antenna-with-loading-coil situation, and not some ridiculous impossible set)? I'll even embed the capacitance in the circuit so you won't be able to say you could measure its current separately from that of the coil. It's a somewhat pointless exercise, but good mental stimulation, like working a crossword puzzle, so I'm up for it.

(I trust you didn't really mean that the coil loses radiation _directly_ to W8JI in your posting quoted above! If every loading coil in the world did that, poor Tom would be getting pretty warm, I suppose. In any event, PLEASE UNDERSTAND THIS: the displacement current from the coil is mostly NOT losing power to the outside world.

Like current in more tangible capacitors, it represents stored energy
that's put into an electric field in part of the cycle, only to be
almost all returned in another part.)

Cheers,
Tom

1007. Magnetic antenna base in pickup truck

Tom, W8JI wrote:
"It isn`t standing waves, it is missing electrical degrees."

That could be sarcasm because it certainly could be standing waves.

In a coil the RF signal travels as a surface wave around the turns of the coil (helix) at about the velocity of light. Hopper`s rule says this is about one foot in a billionth of a second (one nanosecond).

Self inductance can`t magically induce the signal in one end of a coil instantaneously into the opposite end of the coil. Here`s why. Current in the coil induces voltage and current lags the applied voltage by 90-degrees (1/4 of the time required for a complete cyclr). That`s a delay.

Antenna systems produce a reflection from the open-circuit at the tip of an antenna. The incident wave reaching the tip reverses its direction becoming the reflected wave, traveling in the opposite direction from the incident wave. You likely have seen the interference pattern produced by incident and reflected waves on a transmission line in a book. The same pattern starts at the tip of an antenna not terminated in its Zo.

At certain points on the signal path the voltages in the two waves will be in phase and will add, while at other points they will be out of phase and subtract. The points along the path where the two voltages are in phase are points of maximum voltage and minimum current and are spaced one-half wavelength apart. The points along the path where the two voltages are 180-degrees out of phase are points of minimum voltage and maximum current and are also spaced one-half wavelength apart. The distance between alternate points is one-quarter wavelength.

Coil, wire, free-space, whever you have an incident wave and its reflection on a path, you will get this interference pattern on a conductor. So, a loading coil is going to have variations of voltage and current caused by an energy reflection with or without coupling to the rest of the universe.

Best regards, Richard Harrison, KB5WZI

My experience with the black UV resistant ties from many manufacturers is that they do last years in direct sunlight. ... don't even compare with white ties that will degredate within a single year.

Also, a Blue colored tie has been available for some time that is supposedly guarantied to last up to 15 years outdoors. Having used them in years past, it does appear to be true... although they are quite expensive. I forget the manufacturer.

In years past many techs have just used short lengths of insulated 12guage solid wire to hold feedlines to a tower. This is still a valid way to go.... cheaper than ties, and they last very long, too.

Source record: 60952

I have made available from my website the source code of program
COAX_VLF. It may be of interest to transmission line addicts.

Regarding the mathematics involved with the calculations you will not
find any references in your Bibles on which you appear to depend so
much.

But you may, at least, judge from the comments alongside the code what
is involved. That much may be rather obvious.

Roy and others have been criticising me for years about not disclosing
what's behind my programs in the hope of inducing me to disclose the
trade secrets. There are no secrets. Just common sense.

Well Roy, now you have it all. What do you make of it? Can you make
any sense out of it? Don't expect me to spend the next few years
trying to educate you. I havn't the time to spare. In any case I
should expect to be paid at the rate of 100 US$ per hour.

My programs are free to USA citizens. Make what use of them as you
will. And don't quibble about them on the grounds that they are
founded merely on the opinions of a foreigner.

> Yuri da BUm

Yuri,

It is so obvious to anyone experienced with antenna tuners how that can happen I really dodn't think it requires an answer at all.

It is possible to build a "current step up network", or a "current step down network" with two or more reactances, one in series and one in shunt.

What it is NOT possible to do is make a coil change current without that third path to the outside world. Standing waves will not do it, missing antenna degrees will not do it.

Look at a simple L network when you have time, or more closely an L/C/L T network. You will find all laws of charge conservation are met. The current at any junction of one source path into two other branches always totals zero (current in balances currents out).

The antenna is no different. The loading coil in a normal antenna mode might have a somewhat large phase shift in current of the coil has considerable shunt capacitance to the outside world or it might have almost none. This has NOTHING to do with standing waves causing the difference, or missing antenna degrees causing the difference.

There isn't anything mystical or magical about any of this. The only problem is Cecil's theory, Barry's theory, and your idea doesn't fit all systems, and the models and workings presented by Reg, Roy, Tom, Ian, Gener, and others does work in **every** situation.

I can make a mobile antenna that is resonant, change nothing but the coil, and have a mobile antenna that is exactly the same size and still resonant with different currents and phase of currents at both ends of the loading coil. I can do this simply by changing the coil's capacitance to the outside world.

I can prove this.

Black tie wraps do definately hold up longer than regular tie wraps, but
will still give up after several years. Used to use them for Telephone
cables, as well as coax. Wish I remembered the brand name , but if you
Permanent ties, there is a make of METAL- plastic coated ties, that 1) last
forever, and 2), can be reused. Try Greybar Electric , and W.W.
Grainger. Tiewraps are also available in different colors, (they were
used to mark multi -pair telephone cables, in 25 pair bunches), which
are great for clean installs of wireing, in vehicles (blend in with the
vehicle colors), makeing them nearly invisible.

I tried that with my Ranger. Didn't work too well. Never could get a decent swr on the Hamstick (10M). I finally bought one of those mounts that goes in the stake pocket and it worked great. I think the guy advertises in QST. They're about the same price as one of those mag mounts but get the antenna up out of the bed. If you can't find the ad, I'll sell you mine since I don't use it any more (gave the Ranger to my kid).

While in SAC (Strategic Air Command) I was assigned to Lockbourne AFB in
Ohio. We had two of the super large HF Discones. Took up several acres of
real estate as I remember...Not a good choice for Field Day.

Basic unity gain 3 to 30. Worked great. However the two Rhombics beat them
out hands down. And YES I did play on the ham bands with them. And
that's another story.

Unfortunately Richard, to many, including some I am acquainted with, you would be considered much worse than that. Minnesota is not as broad minded as they like to pretend. Religious hangings weren't that long ago here.

And, as the grandson of Polish Jews who, for some unknown reason, hid their ancestry to the point where I was raised Catholic, I am obviously conflicted! ;)

(Continuing the basenote drift, since the basenote thread is pretty
much a mess anyway...)

So it's not clear to me who might be calling whom an unbeliever. Both
Christians and Jews celebrate seder. Maybe it would be those of some
other faith? It's interesting to me--and sad--that so many whose
religion teaches that God is all-powerful and too great to be known
fully by any person are intolerant of others whose religions teach just
the same thing. The intolerance seems as common between sects of
nominally the same religion as between religions. If you can't ever
fully know your god, who are you to say it's not the same god as the
one someone else worships differently, or as someone else worships as a
set of gods?

Hey, we might as well be discussing religion as loading coils...

Ducking,
Tom

I'll bet Panduit was the likely name for them! They are one of the larger makers of all kinds of ties, plastic, metal, etc. I used them for decades. Do a Google search for Panduit Tie wrap and see what turns up.

Morbid curiosity is what keeps me reading it!

This thread reminds me of the time at lunch in school, I put $5 in the jukebox in the lunchroom. I continually pushed the buttons to play "On the Cover of the Rolling Stone", the goofy song by Dr. Hook and the Medicine show. After the 5th repeat, the kids would alternately groan and laugh with each successive play. But most of them stuck around to see just how many times the idiot would play the same song. (turns out 50 - at a dime a pop)

Some of us are now the students, listening to other people sing a different version of "On the Cover of the Rolling Stone".

No, it's just that certain groups of Xians, not a majority but getting
too populous for my taste, seem to think they are the be all end all,
and everyone else is going to HELL, even other Xians, especially
Catholics. And those that aren't Xian, fuggetaboutit, they are all
damned even if they are Good Samaritans and kinder than Mother Theresa,
because they don't belive in the RIGHT THINGS.

Not to worry. All-aluminum antennas are quite practical, as it is the conductivity of the counterpoise/radials that makes it work. Also, please consider the many vertical antennas working off buried copper wires for their ground plane.

If you need magnetic properties on a large aluminum surface (roof?), then cement a small sheet of steel to the aluminum with any handy adhesive. NOT stainless, though; it's generally non-magnetic.

> CL -- I doubt, therefore I might be !

I tried this on a 2M antenna and it didnt work so well. My theory was that since the antenna was not firmly attached to the Al then the capacitve coupling between the base of the antenna and the Al groundplane was off. Fixed the problem by soldering radials to a coffee can lid and placing the antenna on this.

Aluminum is a decent conductor and as a result, it will work. Possibly, the
Lack of the magnetic attractive force was not pulling the magnet very close
or firmly to the plate. This could be helped by putting something on the
bottom of the aluminum / aluminium to get some force and closer spacing,
such as another magnet. You can also generate a lot of posts / re-posts on
the operating theory of mag mount antennas and what this capacitance does...

How would you guys who are stuck in an endless thread of loading coils like to take on 'linear loading'?? are the currents the same at each end of the loading line?? do they cancel completely along the length of the loading line? does the loading line replace so many degrees of the length of the elements or cause some kind of delay???

the antenna i am working on is an m-squared 40m4lldd where, for example, the reflector is 50' tip to tip, about 10' out from the boom there is an insulator, a rod about 9' long connects with a metal bracket on each side of the insulator and folds back toward the boom where they are connected with an aluminum shorting bar that then uses a piece of phillystrand that goes to an element truss support bracket. then of course beyond the insulator is another 15' or so of element, the tips are adjusted to tune the elements.

No idea at all. A friend knows I'm interested in antennas, and sent me the link simply as something interesting. Since things are WAY too quiet here today, I thought I'd post it. ;-)

Were you around this group during the Great Fractal Antenna Debates a couple years ago, John? You've undoubtedly noted references to them in some of the postings in the recent interminable threads.

Cheers,
Tom

Hi Tom, John,

The form shown is a variation of what I called the triangle sweep some
8 years ago. I fed it dipole style, they do similar sections in
parallel against a ground plane.
http://www.qsl.net/kb7qhc/antenna/fractal/Triangle%20Sweep%20Dissection/3dtri-42.htm
The following page shows one construction out 5 iterations in a
planar, not 3 space form:
http://www.qsl.net/kb7qhc/antenna/fractal/Triangle%20Sweep/index.htm
There are as many variations as could be expected, but calling them
"fractal" strains the definition - especially when the debate got down
to claims that every good conventional antenna design was an hidden
example of fractal principles.

If you drill down through the links, they are challenging Walt's
Quadrafilar design of some 35 years ago. Curiously, one frequency
sweep of the "better" of two models had pretty crummy SWR. I couldn't
find the design goal.

I would hope not!!

Here in NH the Jewish community invites the Christian, including Catholic, Community to share the SEDER with them. The SEDER is served in the meeting room at the local synagogue. About 200 non Jewish people, meaning Christian, from the City of Manchester attend. It is an annual event.

The Jewish Community is REFORMED. I do not imagine such an invitation would occur from an Orthodox or Conservative Community. I respect their practice.

In the recent past I have been invited to pray in the congregation with a Conservative Community in Massachusetts. I am humbled. The Rabbi is a holy man.

I searched Google for [borg antenna design nasa] and found lots of
other pictures, including one that has 4 uneven Y elements arranged in
a rotationally symmetrical pattern. It appears to be a monopole
equivalnet (perhaps with circular polarization endward).

I was able to make a magmount work OK with only a steel TV tray.

I decided I wanted an emergency 2M antenna, so I got a ladder and attached the antenna whip from the high point inside my garage roof. The VSWR was awful until I took an old TV tray up and -- *bonk* -- stuck it to the dangling magmount base. Voila! Good VSWR. So, it doesn't take much. If the coffee can lid is what works, then that's what you do!!

i probably didn't do a very good job of describing it, but basically you
take a shorter than 1/4 wave element and cut it in the middle somewhere and
put in an insulator. instead of putting in a loading coil as you would
normally expect you use a shorted piece of parallel wire line to tune it.
in the case of the 40m4lldd the parallel wire line is made of aluminum rod
and is folded back to use it as a truss for the element.

Ah, so the line just reflects an inductive reactance to the center of the element. Is there any reason it shouldn't act just like you'd expect a transmission line to act? If it's symmetric in the antenna field, it shouldn't couple significantly to the antenna (other than through its direct electrical connection). Doesn't sound like it should generate _nearly_ the excitement that loading coils seem to.

Cheers,
Tom

As far as acting as loading element, it is another form of (real life)
loading inductance, so it is similar to loading coil, but worse performer in
the loaded Yagi situation. Have look at the end of my article
http://www.k3bu.us/loadingcoils.htm
where EZNEC plot shows current distribution along the loaded Yagi element,
using loading stubs.

It has been found and published in articles in CQ magazine, where loading
stubs were replaced by the loading coils and the performance of the antenna
like KLM 80m 3 el. loaded Yagi was improved significantly. Better gain and
better and cleaner F/B and pattern. Real modeling and measurements confirmed

that, regardless what the "flat earth - same current" believers claim and try to "prove".
Folding the loading stubs along the elements seems to distort the current distribution along the element and deteriorate its' performance. So you are better off replacing loading stubs with loading coils, and that's what the whole debate about the current distribution, reality and understanding it is about.

Hi Yuri,

As usual, your statement has nothing to do with your link. What is
worse, this EZNEC model is from a third party who is not available to
comment as to the accuracy of your statements about performance.

Even more is the compounding of error at the link:
"G5RV antenna using inductors in the form of loading stubs"
Clearly, then, it is NOT a G5RV.

When we continue with the commentary we find:
"When simple inductance in Eznec is inserted in place of the
stubs, the current erroneously is shown as the same at the both
ends of the inductor."
Clearly, then, the model designer who expected something other does
not know how to design the model. It would seem after several years
of corrections to this error you continue to publish, that you would
have updated your page by now.

It is easy to offer broken solutions. This group sees many of them
that are then used to discredit either the tool or the theory. What
these broken models reveals are the bankrupt designer.

Perhaps you should vet the material from your contributors more
closely.

I worked at an electrical supply for several years, and When Georgia Power was building Plant Vogtle nuclear plant, they must have purchased a truckload or more TY-525-MX (black WP tie-raps). Paperwork had to be traceable back to the factory. We also sold a lot of of Panduit brand tie-raps. I think they are of equal quality.
The black ones have carbon in the mix to retard UV damage. If you take one more step (like put a wrap of tape (3M#88) over the tie-rap) or even paint it - it should give more years of life.
--but like one post mentioned - Panduit -and T&B if I recall both have stainless steel versions.

http://groups.yahoo.com/group/Shortwave-SWL-Antenna/message/9047

Back in the mid 80s there was an excellent electronics magazine
called Hands-On Electronics. In the May/June 1986 issue was an
Article by Ed Noll [W3FQJ] called "Flexo SWL Aerial".

I always wanted to try this Antenna, now I will have the time and
room to put it up.

There are two problems, I have the original Article but I don't have
the Correction for the Control Box that appeared in the next issue.

The second problem is I have looked all over the internet for
Ed Noll -or- W3FQJ. All I get are sites selling his books,
no web or home address.

So, I Need Help.

Does anyone remember the magazine and kept the article
and correction?

Anyone who belongs to other groups will see this post again
and again, etc.

Hi Richard,
I thank you for posting such revealing evaluation of my deficient, misleading knowledge.
Yes, my web site is full of old no good stuff. Even my C6AYB picture is too many pounds old.
Anyone with spec of antenna knowledge can see that "G5RV" is operated as dipole, judging by the standing wave current distribution, and it is not cardinal sin to call it G5RV dipole or vice versa.
If I can get away from deflecting mumbo-jumbo and over holidays, I will start working on the project. Looks like audience here is looking for sticking needles rather than providing answers and suggestions to questions.
The main thrust of question posted here was, should he stay with loading stubs or do something better. I described what was done, and stubs suck, coils are MUCH better and that current distribution is what it is and illustrated in that "butchered" drawing by W5DXP.
I humbly bow in view of your much better, educational posting. I am sure the questioner is fully satisfied with your answers and solutions.

Happy Easter from bankrupt designer

More sobbing. Yuri, if "doing" this had anything to offer you, you
would have done it by now. Others, including myself, have already
posted results, answers and suggestions. We merely wait for you to
either catch up, or pass us.

In light of the many promises of more horsepower, faster acceleration,
and better gas mileage, that has been a long wait.

>The main thrust of question posted here was, should he stay with loading
>stubs or do something better. I described what was done, and stubs suck,

Suck goes right up there with BS that is sold for a dime a truck full.
>coils are MUCH better

How much better? This sounds like a fractal sales pitch.

>and that current distribution is what it is

Zen and BS depress the price to a nickel a truck load.

>and illustrated in that "butchered" drawing by W5DXP.

This confirms my comment that you should vet your references closer.

Hi Yuri,

Now, when we actually "look" at the design at your link, we find we
don't know much about:
1. How tall the antenna is (never said);
2. How long the radials are (never said);
3. How many turns in the coil (have to squint and count and hope);
4. How long the coil is (you gotta guess);
5. What frequency this resonates at (well, actually it doesn't say it
resonates anywhere);
6. What the drive point Z is (as if that mattered)

But we do know that some one can find
7. The current into the coil and;
8. The current out of the coil;
9. which according to breathless reports makes all the difference in
the world,

until
10. I threw away that trash coil, replaced it with a distributed load
(aka shorted transmission line) and boosted the performance.

All of the petty arguing and self-promotion aside, linear loading is just a very poor form of a loading coil. Like any poorly designed system, the ill effects of design shortfalls can range from very small to very large.

As a general rule, linear loading reduces efficiency over a lumped coil of good design. Again the exact amount and the overall effect varies with where the loading is placed in the antenna, how it is constructed, and where and how the loading coil compared to it is constructed and placed.

A transmission line, even a very good one, generally has a Q of someplace around 20-75. The definition of Q I am using is reactance over ESR. Say you need a reactance of 400 ohms to resonate an antenna. Linear or stub loading would add a series resistance of 5 to 20 ohms as loss resistance at that point in the system.

It would take a very poor coil to have that Q, but it can be done.

Depending on where in the antenna you insert that loss resistance, the effects can be large or small. Myself, I avoid linear loading. I'm not a person who likes to gamble.

We have now all seen first hand how a fascination with destroying others really just destroys the ability to learn anything ourselves and to help others learn. This loading coil thing has become a mental illness, like uncontrolled shoplifting. One fellow wrote a nice book on transmission lines and a long argument about amplifiers and a long argument about reflected waves on amplifiers did the same thing.

This stuff is more a demonstration of emotional problems or mental illness than science and education. It's one step below someone going postal and just shooting everyone else in the world who is responsible for his failures and unpopularity!

I hope this post gives insight into how arguing or fixations ruin the educational process, and also sheds light on linear loading. Something for everyone.

Termed by some as the most inexpensive 2.4GHz spectrum analyzer you can buy, the Metageek Wi-Spy USB dongle http://www.metageek.net/index.php has a lot going for it. I recently attempted to use it to judge the performance of various Wi-Fi antennas, with the intent to improve the connection to my local community wireless network access points.

For a source, I used an old D-Link 802.11b Router that I found at a flea market, set to beacon at 3 millisecond intervals with an identification string and a long error correction preamble to provide strong spectrum peaks. At first I located the test antenna and an in-line variable attenuator at the Router output, but leakage through its diversity switch and incidental radiation from its unshielded circuitry took a short cut around the attenuator and produced misleading results.

I then decided a better way to do this testing was to shield the Wi-Spy device in a small box and couple the test antenna to it through my in-line attenuator. I filtered the USB leads with feed-thru capacitors, using 100pf for the +D and -D and 3000pf for the Vbus lines, fastened a dipole antenna to the Wi-Spy case and connected it by a short coax lead to a Type N connector at the other end of the box. I feel the quality of the shielding is related to the quality of the box, and I found a very nice one from Context Engineering Inc. http://www.consite.com/context/cont_circuit.htm It's the 2506 size split body type with extrusions 4.3" long, plain end caps (middle type in the exploded depiction), and is available at Fry's, in the S. F. Bay Area for $10.99 + tax.

Comparing shielded Wi-Spy display levels with a 1/4-wave whip against the USB device directly receiving the test signal showed about an 8 dB coupling loss on the display. But most important is the effectiveness of the shield so that without an antenna, the response in the presence of this normally saturating signal is now indistinguishable from the noise level. The Wi-Spy manufacturer promises to have an improved model with an external antenna connector available this summer, and that will eliminate the coupling loss, but for now, the ability to employ the Wi-Spy either open or shielded answers a variety of needs.

Chuck, W6PKP

OK, I gotta take issue with the part that says,

"> A transmission line, even a very good one, generally has a Q of
> someplace around 20-75. The definition of Q I am using is reactance
> over ESR. Say you need a reactance of 400 ohms to resonate an antenna.
> Linear or stub loading would add a series resistance of 5 to 20 ohms as
> loss resistance at that point in the system.
"

I know that transmission line Q varies all over the place: it's much more reasonable to use it in a resonator at high frequencies than low, and line construction makes a big difference too. To back this up with numbers, I just ran some calcs (actually put together a little Scilab program to run them for me) on four different lines: (a) is RG-8/RG-213 type line with solid poly dielectric, (b) is 75 ohm air insulated coax in an 0.5" ID copper tube, (c) is balanced two-wire line made with 12AWG (~2mm) wire spaced 2" (~5cm) on centers), and (d) is two 0.625" OD copper tubes spaced 3" on center.

For a 1/8 wave section of line shorted at the far end, the calculated impedances and Qs are:

line a, 10MHz: 0.622+j50, Q=80
line a, 100MHz: 0.197+j50, Q=254
line a, 1000MHz: 0.0622+j50, Q=800

line b, 10MHz: 0.35+j75, Q=215
100MHz: 0.110+j75, Q=679
1GHz: 0.035+j75, Q=2147

line c, 10MHz: 0.972+j469, Q=482
100MHz: 0.307+j469, Q=1526
1GHz * : 0.097+j469, Q=4826

line d, 10MHz: 0.124+j270, Q=2170
100MHz: 0.039+j270, Q=6864
1GHz * : 0.012+j270, Q=21.7k

* -- the open wire lines will likely not work in practice quite this well at UHF...

With luck, I got all the calcs right; but in any event, I do expect the Q to go up for a given stub as the sqrt(f), and the Q of open-wire lines to be considerably higher than that of coax with similar conductor diameter, just because the impedance is higher.

The Q of an RG-8-type stub at 10MHz isn't wonderful, but at higher frequencies and with different construction, stubs can work better than coils. There is a range of frequencies where it can be a matter of construction preference: the stub may be easier to integrate into a design, or the coil may be, depending. At high enough frequencies, the stub often is easier.

Also, I want to point out that in a collinear -- a half-wave dipole, center fed, in the center, and an additional half-wave element on either end, coupled through a two-wire-line stub perpendicular to the antenna performs distinctly better than the same antenna in which the stubs are replaced by self-resonant coils, or by a coaxial stub which is made to be collinear with the antenna. That's because the perpendicular stub interacts with the antenna field to excite the right mode on the line to get substantial current in the outboard collinear half-waves. See King for further explanation.

Cheers,
Tom

Why paint radials? Just paint the entire surface for 260 FEET in
diameter. Then you can use a vertical for any band from 160 up with
infinite radials in the circle.

Dave,

Just to clarify, is the 'magnetic/electric field' to which you refer
the same as saying 'electromagnetic field'? I am just trying to
clarify whether it is just how you expressed it or if you are making a
distinctive difference.

Thanks
Buck

Put a steel plate below the aluminum so the magnet won't fall over.
Electrically, it should work on aluminum as the ground will still
conduct when the magnet touches the aluminum. If nothing else, the
capacitive connection through the base of the antenna should be about
the same as it is on the steel.

You are correct in your interpretation of my stumbling words.
The main thing is close proximity to another conductive material will
affect the transmission of energy on twin lead.
I hope that I have helped you. Amateur radio is a fascinating field of
endeavor. Your education does not ever stop.

Wow, good pages, Tom.

Okay now. Your results are pretty compelling, and thanks for the understandable treatment too. I note differing measurements, and a reason for those measurements I'm still reading the pages, but wanted to respond before you thought I was ignoring you.

For the next question, which is directed toward Yuri and/or Cecil, is are your measurements at all related to what Tom reports? Do the numbers correlate?

>line a, 1000MHz: 0.0622+j50, Q=800

I tried these numbers in the line loss calculator at
http://www.vk1od.net/tl/tllce.php using Belden 8267 of 2.475m length
for 0.125 wavelengths and Zload=0.0000000001. The input Z I got was a
little higher at 0.88+j50 (probably slightly different approximation
of Zo used in the calcs), yeilding a Q of 57. The Q is quite dependent
on line length, decreasing as length increases towards a quarter wave.

I suspect this is not a good method of analysing behaviour when the
line elements are field coupled to other radiator elements, the
currents in each leg are not necessarily equal and opposite.

I used to sell the things in large quantities while working for a
Cincinnati electronics distributor. The T&B's are pricey, but for a
reason. They have a stainless steel barb to lock the ty-wrap (their
trademarked name for the devices). It is much stronger than most
competitors molded nylon barb. The black, uv treated ty-wraps work
very, very well. I'll admit that as a radio amateur, I use the generic
uv resistant ones and they also do the job. I generally tape over them.

As a guess, very badly. The aluminum in the paint is in the form of small particles, each probably covered with an oxide coating. So the conductivity would be very poor, even if the paint dried in such a way as to bring the individual particles into contact with each other (which it very well might not).

Yes, the Q as determined by simply taking X/R decreases as you approach 1/4 wavelength, but what you really need to do is resonate it with a capacitance and look at the Z as a function of frequency when you do that. I mean, it IS a resonator if it's 1/4 wave long: it would look like Q=0 there if you take X/R, but of course it's not. If you simply want _inductance_ (i.e. a loading coil), do NOT make the stub close to 1/4 wave long. It's just the same as trying to use a coil for inductance up near its self-resonance.

Also, a point that was in my mind when I originally posted, but failed to put well into writing then, is that as frequency increases, the Q of a solenoid coil will increase about as the square root of frequency...and the size stays the same. But the stub's Q also increases as the square root of frequency, while it's size (length) is directly proportional to 1/freq, and it's shrinking in size.

And thanks for the cross-check on my numbers, Owen. I hacked it pretty quickly, and may have missed a cog somewhere, though I think the numbers are reasonably close. I suppose one of Reg's programs will give you stub impedance, too. -- I think I see why my numbers may be a bit different than what you got; I'll check on it as I have time, though the difference isn't enough to worry me--the trends are still the same.

Cheers,
Tom

You dim witts are calculating Q incorrectly.

Q = X / R

where R is the RF resistance of the conductor and X is the reactance
of the conductor's inductance. You first have to calculate
inductance.

You get a high Q at resonance.

Reg, G4FGQ

So, you state that the ratio X/R is an acceptable way to express the Q of an inductor, why is it unacceptable to express the Q of a two terminal device with an equivalent series impedance of 0.88+j50 (where 0.88 is the RF series resistance of the network and 50 is the series inductive reactance of the element) as 50/0.88 or 57?

Aren't the effiency implications (for that was the context) for a 50 ohm reactance created with a TL stub as described just the same as for a coil with 50 ohms of inductive reactance and 0.88 ohms of series (RF) resistance, ie a coil with the same Q factor?

I figured there must be some problem with it's conductivity if someone
just invented paint to be conductive, but I hadn't tried it.

Owen,
Please excuse my mild scold.

There is only ONE way to calculate Q of a coil or a wire and that is
the way I have described.

It is the ratio of inductive reactance to resistance of the wire, in
series with other. They cannot be measured in combination with each
other.

To do so results in something altogether different like measuring the input impedance of an antenna at or near resonance where the inductive reactance is tuned out by the capacitance and is therefore NOT measured.

It is elementary my dear Watson.

Reg.

Reg, old sot, you need to either quit drinking so much or go back to the fundamental definition of Q. The Q of a coil or capacitor is always an abstraction from the definition. In any event, trying to use a coil or a stub at or near its self (anti)resonance to get an inductive reactance is a really bad plan. You can't separate the self-capacitance from the coil or the stub, so assuming only the reactance from the wire's inductance does you no good at all in that case. As a resonator, it's fine. As an inductive loading component (which is the topic of this thread), it sucks.

Cheers,
Tom

The FAX-30 can handle a variety of antennas. Do you have the FAX-5 active antenna? You can probably connect the M-802 DSC port and the FAX-5/FAX-30 together through a simple coax tee connector. There is not likely to be any interaction between the devices. If interactions should arise, the simplest solution is a coax switch. The switch would be left in the DSC position except when using the FAX-30.

As a precaution, you might contact Furuno and get their opinion. I would think the "dual use" potential for the FAX-5 antenna would be a selling point for Furuno and cause them to give your question a serious response. The question of a separate DSC antenna for the M-802 is likely to be around for a while.

Good luck.

Chuck

Just an afterthought.

Q is dimensionless quantity. Therefore it cannot be measured directly.

It is always obtained as the CALCULATED ratio of TWO independent
measurements or previous calculations.

Its only use is to predict, by further calculation, other properties
of a circuit such as bandwith or voltage magnification. It is just a
convenient intermediary which can frequently be bypassed or done
without.

It can seldom be determined accurately which is a measure of its true
worth. Your guess is as good as mine at high frequencies.

The common or garden Q meter indicates only the resistance of a coil
relative to a standard of some sort. The coil's inductive reactance
is already known, or is related to the capacitor and frequency, or can
otherwise be calculated. Here you still have a pair of independent
measurable quantities.

I'd better stop here. The subject has been over-complicated quite
enough. Here in the Black Country, the weather is beautifully fresh.
Spring is well on its way.

Reg.

1092. Vertically Polorized Omni Slot Antenna

Newsgroup: rec.radio.amateur.antenna

Source record: 60885

If I recall correctly, nope.

A vertically polarized slot antenna will have an azimuth pattern like a dipole.

If you want a vertically polarized omnidirectional antenna, you build a collinear array of vertical elements. If you want a horizontally polarized omnidirectional antenna, you build a collinear array of everything EXCEPT those elements, and feed that. A slot radiates the same way that an antenna element of the same size and shape would radiate, but the E and H fields are interchanged, and therefore has the opposite polarization.

Look up Babinet.

Wow, Matt, that must be close to a record: three uses of "polarized" and they are all spelled differently (and all, um, 'non-standard').

A vertical slot antenna is horizontally polarized. A horizontal slot antenna, while vertically polarized, emits in a standard dipole azimuth pattern. You could try a pair of crossed horizontal slot antennas, fed 90 degrees out of phase, like the "turnstile" crossed dipole antenna. (I don't see how you would actually do it, but you could try.) But why bother, when it's easy to make an omnidirectional vertically polarized antenna in other ways? I'm not saying there couldn't be reasons for doing it, but please let us know what they are.

Cheers,
Tom

It will be an antenna, it will be vertically polarized, but it won't be omnidirectional. It will look just like the familiar horizontal dipole pattern.

That (your afterthought) is much more like it. Thanks.

After all, this is NOT a thread about Q, it's a thread about the effectiveness of different two-terminal devices for use in inductively loading a linear radiator. In that case, the measured impedance, that is, the measured X and R, of the two-terminal device is indeed what matters. Given that we need a particular X, a high ratio of measured X to measured R is advantageous, since the R term represents dissipation. Maybe we should invent a new term and define it thus:

Xiddle = X(measured)/R(measured)

where Xiddle is to be pronounced "Ziddle," and rhymes with "piddle." Or, we could just use the shorthand that W8JI elected to use AND DEFINE in his posting: Q=X(meas)/R(meas).

Just as you say, Q is only an intermediate on the path to something more interesting. It works for me if someone wants to offer a slightly non-standard definition, so long as the definition is clear, as it was to me from W8JI's post.

Thanks for mentioning the Black Country. It was an education for me to look it up. Spring is trying to gain a toehold here, but it's a bit tenuous. Got up to a couple feet of new snow in the hills over the weekend.

Cheers,
Tom

(PS--where do you find gardens that grow "Q meters"? Or are they the things that invade the garden to try to eat the qms?)

Just a second afterthought.

The measured impedance of a 2-terminal device tells you next to
nothing about it. It certainly does not tell you the Q.

To find anything useful about it, it is necessary to shift frequency
and make a SECOND measurement.

So we return, yet again, to a pair of independent measurements or
calculations in order to obtain a ratio.

A ratio has two degrees of freedom. I just love that phrase. I/ve been
waiting for years just to mention it.

Reg.

Hi Dave,

Without some expression of what you might find acceptable, or unacceptable, comparisons are condemned to vagueness, or extreme elaboration.

>with, lets say, a 40-2cd element?

Approx. the same;

>bandwidth?

Approx. the same;

>coupling between yagi elements??

Greater, forcing a different geometry.

>losses?

Approx. the same.

There is nothing in your question that breaks new ground, and substituting equivalent components really only shuffles a few design parameters. Such shuffling may entail considerable tedium in implementation details, but you say nothing of what passes for good or bad. We could equally rend the correspondence bandwidth here into the equivalent tedium of quoting the partial dB differences - that has been good for more than a thousand posts so far.

One of our infrequent correspondents here would substitute metal tubing for bamboo wrapped with metalized mylar film. He couldn't expect any gain in this swap, nor could we point out any considerable loss; but let's face it, the market is not rushing to build antennas this way because there is no economic nor technical justification.

Thus, the only advantage is one of marketing. If you cannot quote a gain advantage, you can at least argue conservation because you are doing Green DXing with Bamboo elements and recycled weather balloons.

So it comes down to a familiar question: What's your point?

:-)

How nice it is to have modern instruments which cover a wide range of frequencies in one simple measurement setup, display the results in any of an array of formats, and even store the measurement results for use in a variety of analysis programs.

(Sometimes, it's even nicer to just escape from them altogether.)

Cheers,
Tom

How does lumped constand circuit theory handle the phase shift through
the inductance? It is certainly NOT zero as your measured.

That's a really strange thing to say, Tom. It happens all the time
inside a piece of coax with reflections. There's no third path to
the outside world, yet the standing waves inside a piece of coax
certainly cause the current to change.

>
> Now, when we actually "look" at the design at your link, we find we
> don't know much about:

Here is the information from my web site as described by Barry, W9UCW:

"Here are some actual measurements of current below and above loading coils.
92" mast, using a HI-Q coil (openwound airdux, 2 1/2"d) with small
thermocouple type meters mounted on the insulated coil support. First for
40m, moving the coil in the mast from base to center to top (with hat) and
reresonating.
Base --100ma below & 66ma above
Center --100ma below & 45ma above
Top --100ma below & 37ma above

Then, same test but for 30m
Base --100ma below & 75ma above
Center --100ma below & 60ma above
Top --100ma below & 52ma above

On a long, skinny 160 resonator with 25pf of top hat and whip, mounted on an
8' mast, I read 100ma below and 65ma above the coil.

Because of the constant claim that this must be due to the fact that the
coil is so big compared to a wavelength, I measured the in and out current
on a TOROIDAL loading coil used on a 20m mobile antenna. It was a 78" base
mast (including spring and mount) with a 38" top whip (including 12" of
alum. tubing for adjustment).
Below --100ma & Above --79ma
When I moved the coil to the top of the mast and made a horizontal "X" top
hat to resonate it back on the same freq, I got
Below --100ma & Above --47ma

So, It happens even in a totally shielded loading coil with miniscule power going thru it! Kirchoff has no laws about current being the same on both ends of inductors. His current law is about one POINT in a circuit and his voltage law is about a closed loop."
... and some significant difference W9UCW in field strength measured between the base and center loading coil:

"The actual difference in signal strength between top and base loading of a 9' antenna is about 16 db (measured) on 75m, but Tom calculates 8db on 160. That's because he assumes the same current in the coil. Actually it's worse on 160 than 75."

> 1. How tall the antenna is (never said);

He said - 92" simulating mobile whip.

> 2. How long the radials are (never said);

Radials laid on the ground are non resonant, doesn't matter much, but there were enough of them (I remember him mentioning at least 32)

> 3. How many turns in the coil (have to squint and count and hope);

Coild is of good quality (aka Texas Bugcatcher), what is important that it was adjusted to bring antenna to 90 electr. degrees - RESONANCE.

> 4. How long the coil is (you gotta guess);

Same as 3, in each test, enough to resonante on band of test (40, 30, 80)

> 5. What frequency this resonates at (well, actually it doesn't say it
> resonates anywhere);

Ham bands 40, 30, 80 and 160 is where they measured the currents.

> 6. What the drive point Z is (as if that mattered)

Not important as long as antenna is resonant on frequency in question. The power was adjusted to show 100 ma full scale on the bottom of the coil and read on the same type of meter on the top.

> But we do know that some one can find
> 7. The current into the coil and;
> 8. The current out of the coil;
> 9. which according to breathless reports makes all the difference in
> the world,
>

Picture of REALITY vs. phasors, distributed baloney, pink electrons, bla, bla ... why it "could not be".
More appropriate assesment would be "significant", which you can judge by his comment about 16 dB vs. 8 dB "calculated" by W8JI
Anyone can duplicate the test and verify the results and claims, instead of displaying their ignorance of reality.

> until
> 10. I threw away that trash coil, replaced it with a distributed load
> (aka shorted transmission line) and boosted the performance.
>

And you did that, and measured it, right?
It has been proven in real life and measurements that "trash" coil performs better in the loaded Yagi design that loading stub (distributed load). It has been done, described and measured by at least three happy owners of modified KLM 2 or 3 el. loaded Yagis on 80. Improved gain and pattern, F/B.

Interesting that the "problems" with loading coils and same current affcionados "know it" based on their (faulty) theories. W8JI attributes his mental state to others to "prove" his "right" which will end up being big egg in his face.

Interesting, that question about loading stubs has "matured" to this also, instead of providing some answers for David.
This is my last contribution to this thread.

Hi Matt

You probably want an antenna with an omniazimuth, vertically polarized pattern and some elevation plane narrowing, ie Gain
It is very easy to build a flush mounted antenna that has the radiation pattern shape equivalent to a quarter wave monopole. Although that would satisfy the specs you have presented, I doubt the broad elevation plane pattern is what you are looking foe since the kbwkf site shows antennas with gain.

Search on Annular Slot for info on a flush mounted antenna with the vertically polarized omniazimuth antenna.

Jerry

Since I think of a halo as a loop in a plane parallel to the ground, it is difficult for me to make a comparison of it to a monopole antenna pattern.

My suggestion would be for you to re-define your needs. There are some really good antenna designers contributing to this group.

>Thanks for the response. Any sort of waveguide based antenna that will work
>as vertical omni?

Hi Matt,

You are bucking the dominant waveguide mode with the design you've
found. Turning the slots will kill it. Just turn the design you've
found sideways.

The alternative is you choose a larger waveguide and introduce iris
apertures inside the waveguide to force a mode that would allow turned
slots. This is all in presumption that you want a vertically oriented
fixture (taller than wide) to give you vertically polarized signals.

Other options include horns and truncated parabolic reflectors - or
something as simple as a 90 degree sweep with a small flared opening
for matching. This would no longer make it omni though.

The coil shown is no such thing.

>with 25pf of top hat and whip

I frankly don't accept the description of "25pf of top hat and whip"
because there is absolutely no supporting discussion, measurements, or
modeling. This is "blue sky" reporting.

>, mounted on an
>8' mast, I read 100ma below and 65ma above the coil.

An 8' mast equates to 92" mast which leaves no room for a whip, that,
or the whip is unspecified.

snip
>a 20m mobile antenna. It was a 78" base
>mast (including spring and mount) with a 38" top whip (including 12" of

Which has absolutely nothing to do with your published page. It is
bad enough to fight for details with one obscure design, to then
australian tag match for two obscure antennas.

snip

>> 1. How tall the antenna is (never said);
>He said - 92" simulating mobile whip.

This is incorrect from the your statements offered above. The ANTENNA
is larger, that much is obvious.

>> 2. How long the radials are (never said);

This does not answer the question.

>what is important that it
>was adjusted to bring antenna to 90 electr. degrees - RESONANCE.

The coil is stock, there was no adjustment made, that is quite
obvious. Further, nothing was resonated. This page's material came
from a jury-rigged set-up for a kangaroo court proof. The antenna was
not resonated the tuning was performed in the shack. Twist enough
knobs to jimmy a current was the name of the game here.

>> 4. How long the coil is (you gotta guess);
>
>Same as 3, in each test,

This does not answer the question.

>enough to resonante on band of test (40, 30, 80)

Yuri, you are pissing on our legs and telling us it is raining. One
coil, one mast, one whip, does not resonate on three bands. You guys
were twisting knobs, not resonating a radiator with a load.

>> 5. What frequency this resonates at (well, actually it doesn't say it
>> resonates anywhere);
>
>Ham bands 40, 30, 80 and 160 is where they measured the currents.

Impossible, the coil is much to small for such a small radiator to
resonate in 160M band, the rest of these claims are equally invalid by
the simple observation of the content at your page and the poor
responses to technical questions above.

>> 6. What the drive point Z is (as if that mattered)
>
>Not important as long as antenna is resonant on frequency in question.

This is simply your way of saying you don't know and you couldn't find
out. Further, nothing was resonant - it would take far more details
that you don't have to make it happen. Again, you just don't know.

>> until
>> 10. I threw away that trash coil, replaced it with a distributed load

Yeah, it'd be great! But unless you are on an aircraft carrier or
battleship, you couldn't fit a discone for HF on a small cruising boat.
The smaller VHF discones wouldn't help you much with HF weatherfax or HF
DSC reception.

One can be made, but the slots have to be
oriented at a slant on the waveguide. The
trick is to make alternate slots radiate
the horizontal component of their slanted
polarization out of phase but have the
vertical component radiated in-phase. This
is a bit tricky and requires a detailed
knowledge of the standing-wave pattern inside
the waveguide at the frequencies of interest
(and therefore is left as an exercise for the
student).

But Yuri, a lumped circuit inductance is a point so it must
have the same current on each side of that point. :-)

It is interesting that, although any coil can be positioned
in the standing wave environment such that the current at
each end of the coil has the same magnitude, only *ONE* of
the many measurements showed the same current at both ends.

Where the heck have you been? The equation for VF is equation (32)

at: http://www.ttr.com/TELSIKS2001-MASTER-1.pdf

Just before that equation for VF is a geometry test for the
coil in question. A 75m bugcatcher coil passes that test.

The velocity factor equation contains helix diameter, turns
per unit length, and wavelength. If we keep those three
quantities constant, the VF of a coil should remain constant
while varying the length of the coil.

The problem encountered previously was we kept the coil length
constant while varying the frequency. That does change the VF.
But this time we are keeping frequency constant.

OK one more time.
We had argument about current in antenna loading coils, one bunch says it is different, another bunch says it is, has to be the same, no way can it be different.

Instead of trying to verify the reality on real antennas, with real, typical hardware and measure it or show that there is something wrong with what we so far presented, we see "theoretical reasons" why it can't be and nitpicking on tangents leading to la-la land, instead of hitting the "meat" of the argument.
Suit yourself. No one said that W9UCW did all the different band experiments with the same setup in the picture. He showed one picture, proof that current CAN be different at two ends of a loading coil, which W8JI and his worshippers claim it CAN NOT BE.
Show us your setup, description and details showing that in all cases current IS ALWAYS (or almost) the SAME!

There is really no point of arguing any more here. I will do the tests and with help of "our campers" we will present comprehensive article on the subject.
I would like to thank you all, including "current nonbelievers" for their opposition, because they highlighted how much misinformation (50 years) and false "science" is out there and helped us to understand the depth and reasons for the current in the loading coil behavior, and especially for the need to set the record straight and help to improve the modeling of loaded antennas.

The rest will be reported on my web site, which I will consolidate and bring up to date in the next few days at www.K3BU.us Then you can nitpick or provide critique. There is no point in arguing, when Cecil asks why is there higher current at the top of the coil and "unbelievers" are mum or keep rattling off their but, but, but...
IT IS STANDING WAVE CURRENT and VOLTAGE along the resonator, get it?
What's next? Denying that there is a daylight, when the sun is out?

I'm not the one designing the antenna. I'd build a collinear. I'm just interested in the properties of the annular slot.

What I mean by "I guess the annular slot is the complement to a halo?" is this:

A halo as I know it is a half wave or so loop broken opposite the feedpoint and in a plane parallel to the ground. It has an omnidirectional azimuth pattern but radiates horizontally polarized radiation.

It seems that the annular slot is a slot in a plane parallel to the ground, with an omnidirectional azimuth pattern, and vertically polarized radiation.

So, is an annular slot antenna a halo cut out of a sheet?

The problem as I see it is that the lumped circuit folk have
no way of knowing when their model has failed them and it is
known to have a failure range. The only way I know of verifying
their model's results is to compare it to the distributed network
model results (or Maxwell's equations) to see if it agrees. That
is something they have proven unwilling to do so they are
really shooting in the dark. In particular, using a signal
containing no phase information to try to measure the phase
shift through a coil and then continuing to report it as a valid
result is really strange. They apparently atill haven't realized
that superposition doesn't preserve all of the information in the
two original waves.

Hi Yuri,

Of all things, "one more time" is boringly trivial. Put it in your sweetheart diary, lock that sucker up, and put it back under your pillow. You have not adequately specified anything, and your comments about efficiency, performance and the rest (if in fact there was anything else) are castles in the air.

>There is really no point of arguing any more here.

And yet this is the entire point of your having posted anything, isn't it?

>I will do the tests and
>with help of "our campers" we will present comprehensive article on the
>subject.

Why would anyone believe in a future of full disclosure when you obviously have such difficulty with simpler topics now?

I offered very simple questions, all about very specific characteristics of ONE antenna. This antenna was YOUR choice to introduce the topic. This antenna was YOUR source of data for all comments that flowed for 10000 postings ever after. You have had more than 2 years to fill in the gaps about ONE antenna. The minimum among these ANTENNA questions was:

1. How high?

2. What drive point Z?

3. What frequency for the combination of all elements?

Now as to the particulars of loading:

1. How long a coil?

2. How many turns in that coil?

3. How long are the radials?

Now as to your efficiency/performance claims:

1. What is the efficiency of a bare radiator without loading?

2. What is the efficiency of the loaded antenna you presented at your page?

3. What is the performance criteria of a bare radiator?

4. What was the performance response of the loaded radiator you presented at your page?

We roll on to test proclamations about linear loading:

1. Let's simply skip this as being obviously tainted by so much missing information as to be irresolvable from more old wives' tales.

Everyone of these questions is easily answered with a simple number.

Everyone of these questions is commonplace discussion for technical examination.

You have answered NONE of these questions. Or was it just one, 92 inches tall? You couldn't even get that one right because the picture ON YOUR PAGE obviously showed a bigger one!

You apparently think you can treat us like fools and that this is enough to prove:

>What's next? Denying that there is a daylight, when the sun is out?

Yuri, you don't have the horsepower to win the race of wits.

OK,
standby for our tests, measurements and data.
Appears that you distrust anything we have argued, but W8JI and equal
current believers need not to present similar data for your microscope.
I will chronicle my experiments and provide data that you question.
I am already washing up my 72 Buick LeSabre and cleaning antenna contacts,
sharpening my instruments and hopefully have enough accurate numbers and
answers for your questions.
Helloooo! We are arguing current distribution in antenna loading coil. Is it
always equal or can it vary? The rest is nitpicking and obfuscating the
question in question.

now really, really SK!

Hi Dan

I recognized that I responded improperly only after I'd sent that post about "you" being the original poster. I may learn to read sometime.

But, back to your question about the annular slot. It is a circular slot cut in a plane, conducting surface. The original Annular Slot design concept may have involved itself with *top loading* of a monopole taken to the extreme. The radiator becomes a ring shaped slot.
My problem with relating the Annular Slot with the Halo, is that the two antennas seem to be of different types.
The annular slot does have the radiation pattern similar to 1/2 of that of the halo in free space.

In the 1950's, the anular slot was used on most military aircraft for ~ 1GHz antennas since it does become flush with the conductive skin of the aircraft. I suspect there are better antennas in use today.

Yuri, I don't know what you are going to prove. W8JI's
and W7EL's own measurements prove beyond any doubt that
the current at each end of the coil is NOT equal. And
the error they made in trying to measure phase using
a signal with unchanging phase is more than obvious.

What you are going to find is that the coil warps the
current profile away from a pure cosine wave as is
shown in Figure 3 at:

http://www.k6mhe.com/n7ws/Loaded%20antennas.htm

The delay through that coil is obviously NOT zero and
the currents at the ends are obviously NOT equal.

Hello:

Have started running cvoax from a receve-only antenna to the house.
The coax has a Polyethylene (PE) Outer jacket.
With this PE jacket, it's upposed to be buriable.

It's becoming a real job for me at my age to dig a slit trench, even a
shallow one.
But, I can easily just lay the coax on the surface, without any reql danger
of anyone
stepping on it, etc. It's in a pretty out of the way area.

I realize that burying it is undoubtedly best, but in a practical
sense, how well does a PE outer jacket stand up if just laying on the ground
?
Would be subjected, of course, to rain, and also buried in snow during the
winter.

Again, it's receive only.

Thanks,
Bob

Cecil,

Why don't you go back and re-read that paper carefully. Pay particular attention to the part where the author says, with emphasis, that the magic formula only works when the coil is near or at resonance.

Your extension to arbitrarily lower frequencies is pure nonsense.

I guess you did not read my complete message. I pointed out the exact location in the paper where this limitation is explained.

I often use the solid-wire trick. I'd note that if you use multiple turns--two or three or four-- it will hold much tighter than a single turn, allowing use of easier-to-handle smaller gauges to hold the same load. It's also a lot easier than a tie-wrap to UNdo when the time comes--no tools required. Easily available in black and white (in the US at least), and other colors if you want. Scales to different sizes well, too. Not that I don't use tie-wraps too, but sometimes they aren't quite the right choice. Oh, and I've recently gotten some easy-release reuseable tie-wraps -- black, and reasonably easy to use, though a larger "knob" of plastic at the latch point. Dunno how many times they can be released/re-used yet.

Cheers,
Tom

I've had coax running though my yard for the past five or six years. It was
just laid across the grass. Gradually it worked it's way out of sight and
show's no sign of deterioration (electrically). We use the yard a lot, I
mow over it, water it, herbicide it, and everything. It survives the harsh
Alberta winters, wet springs, and all. It was just some RG-213 that I picked
up at a flea market!!!!

The most harmful thing to most plastics outdoors is sunlight. I've had some PE jacketed coax outside for many years without noticeable degradation. However, it gets buried in the grass after a couple of years so doesn't get a whole lot of direct sun. Clear PE will deteriorate fairly quickly, but black coloring prevents penetration of the UV light, so I'd expect black PE jacketed cable to last a very long time. Rain, snow, and temperature extremes aren't a problem.

If he will just post the plans to duplicate the antenna, it would give the rest of us something to test. That would be way too easy, I guess.

the other way to burry it, rather than dig a slit, perhaps you can get
a bit of topsoil and just burry it slightly and pack it down after it
will 'seem ' to blend in a bit faster i dunno just a idea obv you
don't want too much extra dirt to create hazard or eyesore but just a
little to soften the edges so to speak

Hi Tom,

If the mood strikes me, I will see how much effort it takes to blow
away his "efficient" antenna. Seeing how he has no answers for its
construction, I can easily impose my own choices like an high E piano
string radiator mid loaded with a squirrel cage over a radial field of
rusting springs from a burnt-out mattress. There should be room for
improvement over that using a coat hanger with distributed loads of
barn nails over the roof of a 1948 Hudson.

Hi Dave,

You never answered:
"What's your point?"
but are you having fun with loading yet?

Hi Myles,

Brass and Iron have the opposite effects for coupling coils. Extending
this abstraction guarantees nothing as you may need a considerable
amount of either to replicate that in an antenna's field.

The metal powder paints are not working well as antennas, copper or aluminium makes no difference. To be able to paint an antenna on an isolating material, I use the silver oxide based paints. Some of these paints can even be soldered on. You can connect the coax by capacitive or direct connection, just make up a small pcb with the gilded side towards the painted surface and it'll work fine. Just glue it to the surface.

You often find this type of paint for repairs of windscreen heater coils.

The normal variants are transparent and a slightly greenish-silverish colour.

You can paint an antenna on a car window if you have a standard glass and none of the new gilded glass with a surface heater or defroster.

However, as the paint is not resistant to wear, like cleaning a window, you have to cover the painted areas with a self adhesive film.

The painted antenna was tested for use in buses and subsequently for VHF and UHF only.
Output power in tens of watts are ok but I did not test with higher powers.

You can also make a precut fractal template and just apply the paint with a roller or a cloth....

Cheers

4 Mhz is not 6.6 Mhz. You're stretching the truth again, Cecil.
Gene is right. Why not just give up. You're not going
to make anything true just by repeating it over and over again.

I think I read in this newsgroup that a ham in the PNW waxed his dipole to keep the rain off. I couldn't tell whether it was just a joke?

In an area notorious for lots of rain, do hams in the Northwest really wax their antennas?

Even when waxed, what is the effect of rain/water on dipole chararacteristics?

> near 4 MHz. Where is all your irrationality coming from?

Cecil,

I guess you can't keep up with your fairy tales.

The exact quote from your message on April 11, at 9:57 am is copied
below. I don't see anything about a bugcatcher coil. Instead there is
some un-described coil stock that requires 37 extra turns in addition to
the starting 32 turns to achieve self-resonance at 4 MHz.

Since the Corum paper highlighted the limitation for applicability of
the magic formula it is possible he thought that the limitation might be
important. However, with your superior intellect it is fully justifiable
to go ahead and accept only those portions of his paper that support
your preconceived notions.

I suppose whatever number you determine will still fall within your 59%
standard of precision.

73,
Gene
W4SZ

[quote]

****
Here's a more valid procedure for determining the
delay through a coil. Changing nothing except the
number of turns, add turns until the coil is self-
resonant at the frequency of use. Frequency doesn't
change. Coil diameter doesn't change. Turns per inch
doesn't change. The *ONLY* thing that changes is the
length of the coil. At self-resonance, we *know* the
longer coil is 90 degrees long.
****

Take that same 32 turn coil and keeping everything the
same, add turns to the coil until it is self-resonant.
We haven't changed the frequency, the diameter, or the
turns per inch. All we have done is add 37 turns to the
original 32 turn coil to make the self-resonant frequency
equal to 4 MHz with 69 turns. SINCE WE HAVEN'T CHANGED
THE FREQUENCY, WE KNOW THAT THE VELOCITY FACTOR OF THE
COIL HAS NOT CHANGED.

In the velocity factor equation, the only variables are
coil diameter, turns per inch, and wavelength. NONE OF
THOSE VARIABLES ARE CHANGED ABOVE.

So we know that 69 turns makes that coil stock self-resonant
at 4 MHz. That would make the phase shift through 32 turns
equal to 42 degrees, making our above 10 degree assumption
false. 42 degrees is probably fairly close to the actual value.
The velocity factor for that coil stock calculates out to
be 0.023 on 4 MHz.

We paint them now, too. The HF whips are all tapered fiberglass shafts (some two-piece) with a single conductor in the center for the radiating element. The resin would be eaten up by the sunlight without painting, but it's special paint that is transparent to RF. There's a need for quite a lot of it, considering all the radomes on the ships for satcom and radar. (The really big ones are just "out there" in the elements but many antennas are in domes.)

Radar Absorbent Material (RAM) is used a lot, and it has to be preserved with antenna paint, too; Regular paint on RAM would reflect just like whatever surface the RAM is applied to, defeating the purpose.

>Only on the south side....

Hi Dave,

I suspect you haven't really seen moss then. In the Hoh and Soleduc
valleys near here, they get 200 inches of rain each year. You can't
see the trees because of the moss. North, South, East, or West sides.
You can't see the ground because of moss, you can't see river bottoms
because of moss. There is only one color - moss. Mt. Baker (yet
another volcano) nearby sets records for snowfall. Seven years ago it
stood at 95 feet of snow. Mt. Rainier (yet another volcano) averages
60 feet of snow each year. When you fly into Seattle, you can see at
least 4 or 5 volcanoes (there are more).

Seattle isn't "that" rainy though, we only had 27 straight days of
rain a while ago, got one day of sunshine and then went right back to
rain. This last month I put in rain barrels and found I had to empty
200 gallons of water every other week and that was only for soft
showers, what we call "spitting." Only tourists use windshield wipers
in this.

So, there's two problems with waxing antennas (sounds like what girls
would do). You'd spend too much time in the rain to no purpose
because the rain would wash it off anyway.

73's
Richard Clark, KB7QHC
caveat: we only boast this to frighten Californians away - no one who
lives here is really impressed by the rain.

I would prefer a radiator made from half inch PVC filled with a dilute
sodium chloride solution. If you put a valve at the bottom, it's a snap
to adjust resonance.

Tom Donaly wrote:
> 4 Mhz is not 6.6 Mhz.

Nobody said 4 MHz is 6.6 MHz. 4 MHz is 60% of 6.6 MHz and is therefore near 6.6 MHz. Dr. Corum says the lumped constant model fails at 0.04 wavelength. In his other paper, he says if the length of the wire used to wind the coil is 0.06 wavelength, it's time to switch over to the distributed network model. A 75m bugcatcher coil uses more than 0.06 wavelength of wire.

Please explain the physics behind the velocity factor of a coil changing radically just because you cut it in half - assuming all other parameters are kept at the same value.

Your model is known to fail at a point but you guys have no clue where that failure point is. You just have faith that you will never reach the failure point. But what if you have already reached it?

As I said previously, it's only a pure cosine wave for a thin-wire dipole. NEC handles more than thin-wire dipoles.

The coil adds a bulge to the thin-wire cosine wave but the overall envelope is clearly visible.

The coil being discussed is a bugcatcher coil modeled in EZNEC.

> Since the Corum paper highlighted the limitation for applicability of
> the magic formula it is possible he thought that the limitation might be
> important.

The limitation that Dr. Corum highlighted was the failure of the
lumped circuit model when the coil is self-resonant. He says that
when we are within 17% of self-resonance, the lumped circuit model
fails. Have you anything besides faith to prove that your model
is valid within 60% of self-resonance?

Please describe the physics behind a radical change in velocity
factor (at the same frequency) when a coil is cut in half.

Cecil,

You have really lost it. I gave you the exact quote, and you then proceed to talk about something else.

It appears you did not really read and understand the Corum paper either. The portion I referred to you had nothing to say about lumped circuits or distributed circuits. It was merely a step in the mathematical analysis that leads to the magic formula for Vf. If you ignore the important limitations on the math analysis it is likely that any conclusions drawn will be incorrect.

So let's throw the topic back to you. A straight wire has a Vf near 1. A resonant coil has a Vf of 0.01 or 0.02. So where and how does the Vf transition occur? For a coil of one turn? For a coil with a length of 15% of the resonant length? At some other coil length? Is the Vf transition abrupt or smooth?

You seem to understand everything about coil Vf, so these should be easy questions for you.

73,
Gene

At least where I live, FM20, I don't see thin elements as a big deal. I have
had a KLM 50 - 7 LD up for over 20 years with no signs ef element damage. As
for bandwidth, 50.0 to 50.25 is really all you need for CW and SSB.

==========
Dear Cec,

What is the failure mode?
Is it a sudden catastropic failure?
Or does it fail very slowly, gradually and gently?

What is Dr.Corum a doctor of?

From your quotes he sounds like a Quack. Or is he a Witch?

What does he have to say about Fractals, E-H and the other wierd
contraptions?

How many other worshipping followers does he have besides yourself?

Or are you just pulling our varicose-veined legs?

All rhetorical questions of course. Answers not required.

Your old, well-intentioned pal, Reg.

==========

With ice and snow the SWR, if it's not perfect, and it never is, is
just as likely to improve as it is to get worse.

It's radiating efficiciency what matters. And the SWR is no
indication of this. A change in SWR is just another symptom of the
presence of ice or snow.

To see how much efficiency has deteriorated you would do better just
by looking out of the shack window at the weather conditions. From
appearances it is seldom as bad as you think!

After all, all the SWR meter tells you is whether or not the load on
the transmitter is matched to 50 ohms. Just readjust the tuner if you
have one.

Reg.

It works. We Californians are allergic to long periods of unremitting
rain. It washes off the thin veneer of civilization.

Gene Fuller wrote:
> You have really lost it. I gave you the exact quote, and you then
> proceed to talk about something else.

Your quote doesn't mean what you think it means. The velocity
factor equation is appropriate for quarterwave resonance *and*
any other length at the same frequency. The graph in the next
column over shows coils of 10,000 turns per wavelength. It does
NOT limit them to any length so your argument is bogus.

Their goal was to find a VF equation that worked for quarterwave
resonance but it works for a lot more than quarterwave resonance.
It holds for any length as can be seen from Fig. 1.

> So let's throw the topic back to you.

Too late, I asked you first. Where are the laws of physics
to back up your assertions? Certainly not contained in the
Corum papers. Please provide some reference that asserts
that the VF of a coil varies with its length while keeping
all other parameters constant.

The coil being modeled is 48 turns per foot. The wavelength
is 246 feet. 48*246 = 11,808 turns per wavelength. That's
on the Corum chart. There is NO minimum or maximum length
requirement or constraint. According to the paper, the velocity
factor is within 10% no matter what the length of the coil.

So holding all the variables constant in the velocity factor
equation and changing only the length is a valid way to
calculate the approximate delay through the coil. It's the
best way that we have so far. It is infinitely better than
using a signal with unchanging phase to try to measure
phase shift.

> So where and how does the Vf transition occur?

Just as in a transmission line, a VF transition occurs
at an impedance discontinuity. For a complete helical
antenna, there is no impedance discontinuity. For an
antenna containing a coil and wire, there is an impedance
discontinuity at the coil/wire interface.

Reg Edwards wrote:
> What is the failure mode?
> Is it a sudden catastropic failure?
> Or does it fail very slowly, gradually and gently?

It fails gradually. It fails earlier for phase calculations
than it does for magnitude calculations. That's why the
phase shifts reported here are completely invalid. Here's
how it goes:

1. There is no phase shift through a lumped inductance.

2. The standing wave current with its unchanging phase
shows zero phase shift through a loading coil.

3. Therefore, a real world loading shows zero phase shift
just like a lumped inductance.

The proof was preassumed and invalid measurements support
the preassumed proof. Case closed!

The design of the yagi (element lengths and spacing) has far greater
influence on the bandwidth than the element diameter. In other words,
a wire yagi could have wider bandwidth than one made with tubing.

It's also hard to say that larger diameter elements always survive
ice and wind better, as there are many variables: taper schedule, tubing
thickness, etc.

Cecil,

The "quote" was from your message, not the Corum paper. It is highly likely that it does not mean what I think it means. It probably does not even mean the same thing to you after a few minutes.

As for the Corum paper, would you be so kind as to point out the page where it is written:

The velocity factor equation is appropriate for quarterwave resonance *and* any other length at the same frequency.

I found the section that says the formula is appropriate at resonance, and I must have missed the part that says the formula works for any length as long as the frequency is maintained.

You still have not explained at what point the transition from Vf ~ 1 to Vf < 0.02 occurs.

73,
Gene

I already told you - same page, Fig. 1 where that VF equation is
plotted. There is absolutely no reference to coil length in Fig. 1.
The only independent variables are the diameter/wavelength ratio
and the turns/wavelength ratio. For any length coil with the above
fixed parameters, including frequency, the VF is constant within
10%.

> I found the section that says the formula is appropriate at resonance,
> and I must have missed the part that says the formula works for any
> length as long as the frequency is maintained.

"We have found that this expression gives acceptable results (errors
less than 10%) for most practical applications that involve wave
propagation on helical resonators ..." Absolutely no mention of
14WL self-resonance.

> You still have not explained at what point the transition from Vf ~ 1 to
> Vf < 0.02 occurs.

It is explained perfectly in Fig. 1 where the VF scale goes from
0.0 to 1.0. Come over to my house for a beer and I will teach you
how to read that graph.

Exactly as would be expected, holding the diameter/wavelength ratio
constant, as the helical is wound tighter and tighter, the VF decreases.

Cecil,

Oh darn! There's that nasty reference to "resonator" again. You really need to read the paper again and attempt to understand it.

Try the left-hand column on the page for the fundamental mathematical limitation that underlies everything else on the page, including Figure 1.

Since this is a question of literacy and not technology there is little more to be said here.

73,
Gene

And, here in DM09, , Elevation 5K feet, with winds in excess
or 70 MPH, my 7 El holds up just fine , except for when the TOWER
came down! But, with a total of 49 states worked,under this call
find it totally adiquite- and looked at the specs for this, vs.
the "JHV" 7 el, think the JHV is about a foot longer, has better
F/B, and .2 (2/10) dB extra gain! Think ANY of these would work fine
for all but the most discriminateing op (and never know the difference)!
and also, consider that get iceing here, maybe 2 inch dia. , and NOT
raining aluminium (elements falling off), like SOME other brands!

"Accept"? The M2 antennas work hunky dory where all the activity is.

> If Ice is not a problem great! Can't ignore it here.

I've used my 6M5 in Finland and here in West Virginia. Ice and snow
don't seem to change anything.

> One problem with M2s is that the cable to element coupler is
> sometimes a problem.

I got my 6M5 in '88, part way through an assignment in Guinea-Bissau.
It lasted through three additional African assignments with heat,
humidity, dust and rain. It went through three years in wintery
Finland, all with the original element to cable coupler. A 2003 tower
failure made it necessary to replace two directors. While I was at it,
I replaced the original coaxial balun. That's pretty good service. In
fact, after the tower collapse, I replaced the Cushcraft 2m and 70cm
boomers with similar M2 models.

Phil,

I have a pair of M squared 6M5's stacked at 140 feet, and don't have
any bandwidth, ice, or other problems.

They work just fine, and hold up well. Mine have had 1/2 inch of radial
ice and at other times winds over 100MPH. No problems.

No feedline or feedpoint problems, and I run a full kilowatt or so of
RF at the antenna even on CW.

HAR! Almost. The short version is that they ran the tape to the point that they wanted to edit, then put disclosure fluid on the spot to find the magnetized recording lines, and under magnification found the place they wanted and sliced the tape at that point. The footage that was spliced in was put in, and then the process continued. If the cut and splice wasn't accurate, sync would be lost.

Next time you watch an old TV show (pre-early 60s) note that there are not tight cuts.

Gene Fuller wrote:
> Oh darn! There's that nasty reference to "resonator" again. You really
> need to read the paper again and attempt to understand it.

Uhhhhh Gene, a 75m bugcatcher coil is a "resonator" that
resonates an 8 foot mobile antenna on 75m. Take a look at
Figure 2 in Dr. Corum's paper. It looks just like a top-
loaded 160m mobile antenna.

> Try the left-hand column on the page for the fundamental mathematical
> limitation that underlies everything else on the page, including Figure 1.

There is a test equation to see if a particular coil is
outside the fundamental mathematicdal limitations. A 75m
bugcatcher coil is less than half the limit value.

Let me show you how to use Fig. 1. The coil that we have
been discussing is 6 inches in diameter and has 4 turns
per inch. That makes D/lamda = 2.0 x 10^3. That's just
about in the middle of the graphic. The turns per wavelength
is 48*246 = 11,808. That's just to the left of the left
hand curve. Reading the velocity factor from the graph
gives about 0.03 for that coil. It's a piece of cake
if you understand the physics involved.

w8ji@akorn.net wrote:
> I can't believe you are still trying to get Cecil to actually read the
> paper he is misquoting.

Unfortunately for your lumped circuit religion, I am not misquoting anything. Page 4 contains a test to see if a coil falls within the limitations of the velocity factor equation. A 75m bugcatcher coil is less than half the upper limit.

Here's the calculation: 5*N*D^2/lamda < 1

N is turns per unit length and D is the diameter.

5*48*0.5^2/246 = 0.24 < 1

Therefore, the graph in Fig. 1 is valid for 75m bugcatcher coils and the velocity factor is around 0.02. The VF equation yields the same value as the graph.

The lumped circuit model is known to fail. Dr. Corum knows where it fails. Most people on this newsgroup don't know. And when it does fail, the distributed network model gives valid results.

Why would you ever choose a model known to fail without knowing where it fails when you could be using a model known to be valid?

It could be one of two things that come to mind right now.

The first thing is a set of bus wires to feed the internal
heating grid for de-icing the canopy. The other wires that
do the actual heating would be too small to see.

The second thing that I can think of is the possible method
that is used to get the canopy out of the way for an ejection.
I believe, and could be wrong, that some of the canopies do not
actually slide to the back to allow ejection but the canopy itself
is shattered by an internal linear explosive that allows the crew
to leave the plane without contacting the canopy.

Nothing much has changed, OM. I've been doing this since early 1962 and it's almost all the same except that the gear is fancier. More and more of the painted stuff gets sent out to be powder coated or flame sprayed -- techniques that have come into use since our first days -- but you still have to keep gummint property and salt air on opposite sides of some barrier. We have shore maintenance shops devoted to Corrosion Control in every Navy port.

They talk about a coupler in Section 7, but are not specific. As I dislike t-connectors on principle, I would use a 50-ohm power divider. They correspond to the action of a TV cable splitter but an actual TV cable splitter would not perform well at HF and below You can build your own in a metal project box, using a Y configuration with a 25-ohm carbon resistor in each leg to maintain some semblance of impedance matching. Maybe you can find an old TV cable splitter that you can gut for the purpose. For receive-only, the antenna length is not critical. I recall Navtex specifies a whip antenna of several meters; Navtex is on two freqs near 500 KHz, so it's not far from the AM broadcast band. Hm-m-m ... What does a car radio antenna look like???

Good luck.

Tom:

Unless I miss my bet, it seems you are referring to what looks like wire embedded in the top of the canopy, but is really small diameter detonation cord (det cord) and it is used as one of the first events in an ejection sequence.

In the type I am describing, the transparent canopy is shattered by the explosive in the det cord, the slipstream carries away all the small bits of plexiglass and the ejection seat containing the pilot follows a few microseconds later. In some types, the whole canopy is blown clear of the aircraft before the seat goes. An example of this can be seen in the picture of the ASAF Thunderbirds F-16 ejection at http://www.ejectionsite.com/ a search on ejection seats might make for some interesting reading.

Hopefully, I'm not leading you on a wild goose chase.

Regards,
Lee

I tried to, but I see it did no good at all.

I have a Force 12 80 and 40 meter linear loaded Yagi.

The Q of the loading sections are terrible. They are thin aluminum wire
of some sort of alloy that makes them hard.

For the typical reactances produced by that loading system Q (reactance
over ESR) is well in the sub-100 range.

That's why you can take even a fairly poor loading coil, replace the
linear loading, and have the same perfromance. Or you can make a good
coil, like airdux or BW stock with number 12-14 wire, and make the
antenna work better (IF you can keep it from falling apart in the
wind).

The results of linear loading depends on where the linear loading is
installed and how it is constructed, but the general rule is if you
take the very same size and material conductors and wind a coil it will
work better.

Now I suppose we can talk about UHF antennas, 1/2 inch copper tubing
stubs, Cecil's imaginary reflected waves, quote Harrison's book
collection.....but that's how the Force 12 linear loaded 80 and 40
meter antennas I have work.

That's why they are laying in a pile with waddled out holes near the
rivets and all that lossy linear loading wire wrapped up in a ball,
waiting the be rebuilt into good antennas.

Impedance matching shouldn't be an issue for the OP since he is using an active antenna. A short whip at at 500 kHz presents a terrible mismatch to a "50 ohm" receiver input so the active antenna matches impedance, usually with an FET source follower, and may provide gain as well. The more interesting question is how the active antenna "works" over the entire HF range without retuning!

The potential problem with a tee is that it provides no isolation between the two receivers. But I doubt that would be a problem. All it takes is a couple of dollars and a few minutes to find out.

Well, you can't waste Bud. For those that appreciate real beers and lagers, Budweiser is universally shunned. One batch at the factory, add preservatives, flavor enhancers, artificial flavorings, and voila! You have 10 different kinds of Bud. Or so I've heard. ;)

I'm not sure about the conductivity. It might be worth buying a single to test.

Sorry, Tom, I cannot take credit for reflected waves on standing wave antennas. That you didn't realize that you were dealing with a standing wave antena is part of your problem.

Kraus: "A sinusoidal current distribution may be regarded as the standing wave produced by two uniform (unattenuated) traveling waves of equal amplitude moving in opposite directions along the antenna."

Balanis: "The sinusoidal current distribution of long open-ended linear antennas is a standing wave constructed by two waves of equal amplitude and 180 degree phase difference at the open-end traveling in opposite directions along its length."

Balanis: "The current and voltage distributions on open-ended wire antennas are similar to the standing wave patterns on open-ended transmission lines."

Balanis: "Standing wave antennas, such as the dipole, can be analyzed as traveling wave antennas with waves propagating in opposite directions (forward and backward) and represented by traveling wave currents ..."

Cecil,

Selective quoting can have the same effect as misquoting. If one goes back a few words in the same long sentence it can be observed that the more complete limitation is stated as:

"... an approximation for M has been determined by Kandoian and Sichak which is *appropriate for quarter-wave resonance* and is valid for helices with 5*N*D^2/lambda < 1 ..."

[emphasis was in the original]

You apparently choose to accept the second half of the condition while ignoring the first half. In most cases the "AND" construction means both parts apply.

Do you really think the Vf is dependent only on the turn density and not the number of turns? Corum never says such a thing, since the number of turns is dictated by the resonance requirement. How far down does your magic extend? To half the turns needed for resonance? To one turn? To less than one turn? Where is the transition in Vf from the ~1 for zero turns to ~0.02 for a resonant coil?

For anyone still reading who is bored (everyone) or confused by this topic (perhaps) the importance to the subject at hand is that Cecil has mis-used this reference paper to "prove" that the 75 meter loading coil replaces approximately 45 degrees of the original unloaded quarter wave antenna. After his long struggle to prove his point with modeling, and achieving only 10 degrees of phase replacement, he abandoned that

approach for this latest futile attempt. The "missing" portion of the test antenna is about 75 degrees, so 45 degrees would barely squeak in under the 59% precision rule.

1231. Choke Balun Torture

Newsgroup: rec.radio.amateur.antenna
Date: 2006-04-20 15:17:11 UTC
From: "n3ox.dan@gmail.com" <n3ox.dan@gmail.com>
Message-ID: <1145546231.626871.112300@e56g2000cwe.googlegroups.com>
Source record: 60723

I've constructed a choke balun from a big toroidal core I had lying around, abt 3.5 inch O.D., 2 inch ID, unknown material, measures about 125 ohms pure inductive at 7 MHz with 3 turns on it, so I figured that 10 or 12 turns would be an effective 7MHz choke*.

The coax is RG-55 double shielded RG-58 size, solid center conductor, solid polyethylene dielectric.

I wound the coax pretty tightly for neatness; each turn is probably only 1 inch inner diameter.

Is this too tight? With a 47 ohm resistor in series with the output wires (I figure about 0.05 microhenries there, it's a few inches of wire), I get what I think are more or less expected results right now. I've been playing with one of Reg's programs to see if the impedance at the input side of the balun jives with the termination, and I think it does, but I can't just go up up up in frequency with the MFJ-259 to see if I've affected the *cable* impedance unless I cut off my weather sealed, heat shrinked, and Anderson Powerpoled coil tap wires and put on a BNC and terminator.

So I wonder about the longevity of the thing. How tight do you coil your toroidal choke baluns?

*Another question, figured I'd put it at the end. What's the impedance/length of the 43 material core that fits over RG-58 down at 7-10MHz. Amidon and Fair-Rite sites have some spot measurements higher up that I've found, but I'm not turning up charts for all of HF.

I know 43 material is not used so much for low-power HF choke baluns because of reduced per-bead impedance, but I got a big box of them for free, so it's just stringing effort on my part to make a bead choke for 40m.

73,
Dan

I have already explained that to you twice now, Gene. This is the third time so listen up. They were looking for a formula "appropriate for quarter-wave resonance" and they found one that works for lengths other than a quarter-wavelength. If it worked *only* for quarter-wave resonance, they would have said so. You are confusing a mutually inclusive statement with a mutually exclusive statement.

> Do you really think the Vf is dependent only on the turn density and not
> the number of turns? Corum never says such a thing, ...

Already asked and answered. He certainly does imply such a thing in Fig. 1. The VF is dependent only on the turn density and the diameter of the coil. The number of turns affects the length of the coil. The length of the coil is NOT a parameter in the graphic nor does it appear in the equation.

Does a 1/4WL transmission line have a different VF when it is increased to 1/2WL?

> Where is the transition in Vf from the ~1 for zero
> turns to ~0.02 for a resonant coil?

Already asked and answered. If you cannot read Fig 1, then you have a problem. The VF in the graphic goes from 0.0 to 1.0.

> After his long struggle to prove his point with modeling, and
> achieving only 10 degrees of phase replacement, he abandoned that
> approach for this latest futile attempt.

The voltage was 67 degrees out of phase with the current so we weren't dealing with traveling waves. That's why I abandoned it - because I was on the verge of making the same mistake that W7EL and W8JI already made - trusting measurements in the presence of standing waves.

> The "missing" portion of the
> test antenna is about 75 degrees, so 45 degrees would barely squeak in
> under the 59% precision rule.

Once again, there is no "missing" portion of an antenna. The delay through the loading coil is what it is. There is absolutely no requirement that it be
a certain number of degrees.

What is required is that (Vfor+Vref)/(Ifor+Iref) be purely resistive at the feedpoint. There is absolutely no requirement for the antenna to be 90 degrees long. That is just another one of your many strawmen.

I am trying to zero in on the technical facts. What are you trying to do?

Your comments indicate that have an unusual interest in the homosexual
lifestyle. By appearing to be virulently anti-homosexual you come
across as trying too hard to convince us that you are heterosexual.
Possibly you need to convince yourself first that you don't have
homosexual tendencies before trying so hard to convince others.

Really, it's ok if you are. Just accept yourself as you are and
everything will be fine - eventually.

well you facts are in error

I said his conclusions were wrong

The ARRL had no real choice in allowing LARC to advertise the cloesets
it had to a choice was a long and expensive legal battle that it would
likely lose

as to the rest I refarined from comenting on the posters obvious sexaul
issues becaus ethey were
A) obvious and
B) simple the run of a flase premises which by the GIGO meant they
rest was garbage

Take the VF=0.02 resonant coil and divide it into two equal
coils. Do you really expect the two coils to have VFs of 1.0
while their end-to-end combination results in a VF of
0.02? Please quote the laws of physics that allows such
to happen.

Cecil,

You just contradicted yourself. Yes, indeed, Fig.1 shows Vf going from 0.0 to 1.0. But as you pointed out, there is no dependency on the number of turns anywhere in the chart axes or in the plotted data. It would be useful if you looked at the caption on that figure to attempt to understand what is actually being plotted. The vertical scale is Vf and the horizontal scale is D/lambda. The parameter attached to each curve is "N", which is defined as the turns per wavelength.

We would expect a very short coil to look like a straight wire, with a Vf near 1.0. How does the Vf transition to 0.02 for a resonant coil occur? That transition is most certainly NOT shown in Fig. 1.

Hi Gene,

To ask about those still reading, there is one very good reason why
the thread persists: topic drift as your post has just raised the
opportunity to:
1. argue the original quotation by shifting authors;
2. argue the subquotation in terms of ANDing where his sum of the
parts never equal the whole;
3. respond to "do you think the Vf" in terms that diverge from your
yes/no;
4. argue no one uses a one turn coil load for 160M (this is all
getting too easy to dissemble);
5. discuss transitions when you obviously don't believe they exist
(more arguments over inconsequentials);
6. counter-claim old claims (aka correcting what he would call your
bad context);
7. argue models (he has already questioned EZNEC's capacity in some
form - you will only tread that old ground once again);
8. fight over "missing" portions of the antenna - Cecil can prove he
never "exactly" said it did!;
9. ... and more through finer parsing than found here (and it is
guaranteed to be found, that has been amply demonstrated when you feed
the troll).

Those exchanges are like watching someone chase the clown in a
revolving door with discarded lines of attack flying out like grass
clippings from a lawn mower.

Cecil has never been able to hold his ground to one point when I've
drilled down instead of following the outrageous. No one want to
abandon the only true content, the comedy; but, really, the knots of
argument are far more deterministic than the technical issue
supposedly being discussed.

Cecil,

What is the mystery? Have you never seen a response curve for a resonant condition? It is not exactly linear.

You are the expert on Vf. You assert without proof that a half-length coil has the same Vf as the full-length resonant coil. OK, even if I accepted that supposition, what happens at a quarter-length or at a tenth-length? I am simply asking how the function changes between the "known" limits of 1.0 and <0.02. You have repeatedly ducked any sort of answer.

There you go again. We are not talking about very short coils.
We are talking about big honking 75m bugcatcher coils. We
are talking about taking a 1/4WL self-resonant coil and cutting
it into two equal sized coils. The VF is not likely to change by
more than 10%.

> How does the Vf transition to 0.02 for a resonant coil

Of course it is shown. Draw a vertical line at 10^-3. The 10k
turns per lamda coil has a VF of 0.07. The 50 turns per lamda
has a VF of 0.86. Exactly the same principle applies to your
question.

Richard,

I gave up on this thread a couple of weeks ago, largely because it had drifted. However, it came right back to the original topic when the velocity-factor-based 45 degree replacement item came up. Cecil and his friends now deny they ever said anything about coils replacing the "degrees" of missing wire, but they keep coming back to the same position again and again.

Showing my ignorance (or perhaps deteriorating intellect?) again:

I am attempting to compare the gain of a full size (1/4 wave) vertical
to various shorter verticals at 160 meters.

I am looking at the gain in dbi on the 2D plot. I see 1.39 dbi for the
full 1/4 wave and I see 1.52 dbi for the 28 foot version.

I don't believe the shorter antenna has less gain. Where am I going
wrong?

On the contrary, I just posted the answer for the third time. The
Y-axis answers your question. Hold the diameter/lamda ratio
constant and vary the turns/lamda to answer your question.
Do I have to plot zero turns/lamda for you?

Hi John,

Well, at a minumum, your statements conflict from one paragraph to the
next. That is one indication of something wrong even before we
consider the numbers.

Unravelling that knot, and taking only the first paragraph, yes that
looks wrong (in comparison) too. On the third hand, even if it were
true 0.13dB is something you will never measure accurately in your
lifetime. Even more, you would never perceive it.

Your question should be more of the nature, "how did I misread the
results?" to which we could respond to the tenor of your opening
statement:
>Showing my ignorance (or perhaps deteriorating intellect?) again

Perhaps if you were to explain how you got here instead (the problem)
of what you found (the symptom).

Skirt Chaser,

So convinced of your position, you didn't post with a real name. One thing we all can agree on: The ARRL did not hide its political position.

I want to go on record as embracing the ARRL's move, a reason that I just may join after all these years. I guess I first need to identify myself as "normal" heterosexual, although sexual identity ought not be relevant to one's standing or reputation in life.

The terms of conduct you use are appalling, homphobic imaginationl. How can youi pre-suppose what two consenting adults do privately? Do we pre-suppose what heterosexuals do? Of course not, realizing sexuality is unique.

The only act that is obviuos becomes so by the birth of children, otherwise sexuality is a private matter. And on what basis do you connect children with homosexuality, which abuses pale in comparison to heterosexual abuses with children.

A compelling example, by no means alone, is the recent spate of female teacher abuses of male minors. To draw the example further, the reality of this teacher abuse by no means speaks for female teachers in general, any more than homosexuality equates to abuse of children.

Your post, to me, seems so rife with homophobia and prejudice that you seem mentally unbalanced. Of course, I could be wrong and I could be the unbalanced one. In any case, I wish you well and hope you will begin to feel the integrity of your words suffcient that you identify your posts by real name and call.

Hi Gene,

Well, you will never find a definitive quote to pin to Cecil that the
45 degrees is replaced by a coil. That ain't gonna happen. Cecil
doesn't need to say it when so many are ready to interpret this from
his crafted comments which lead to no other conclusion.

As for Vf, you can argue that 'till you are blue in the face, but
given a 59% slop factor that Cecil embraces, any of his computations
can transform gold into lead.

So, the comedy is the only thing left, and it comes like a wildcat
gusher if you simply drill down - on one point - and he is left
claiming the most absurd things that are self-negating (you don't even
have to argue the point it gets so funny). It doesn't take very long
either.

Take a look at the phase angle between the feedpoint voltage
and the feedpoint current for the 28 foot version and try to
figure out an efficient matching network. That phase angle
is ~89.95 degrees. The feedpoint voltage is 1400 volts for
only 1.2 watts input. The feedpoint impedance is about
1.2-j1400 ohms.

Try using the helix feature to install a loading coil in the center
of the 28 foot antenna. The gain will drop as expected but the
feedpoint impedance will be easier to match.

Well, in fact it does not (and nothing shown on the graph along that
ordinal line does).

Do we now hear the pity card played about poor eyesight? Or the pity
card played about poor computational skills (ï¿½59%)? Or the pity card
played for the confusion of old age when two coils are substituted in
the old shell game?

Oops! Thanks for the quick response!
That should have read "I can't believe the shorter antenna has MORE gain". I am not normally troubled by such small differences in db's but for that small of a gain difference and that large of a physical difference (104 feet!) I am certain I have missed more than a decimal point.

The tone of the message was intended as apologetic. I really hate to bring dumb questions here to the experts but other than my books and the Internet I have no where else to go with them. I also hate to take the dumb questions to Roy directly for fear I will wear out my welcome with him.

What happened should be obvious. I correctly used the 10^-3
vertical line for the first one and accidentally used the 0.01 vertical
line for the second one.

The first observation is OK. The second should be changed to
500 turns per lamda with a VF of 0.96.

The same principle still applies. As the turns/lamda increases,
the VF decreases while keeping the diameter and frequency
the same.

I don't find the Helix feature in my copy of EZNEC+ V4.
I believe I can get the same results by inserting an appropriate load.
It will just be a little more cumbersome.

I was not aware that the feeding of the radiator was affected by the
driving source. My "lab models" require a base inductance to get the
radiator into a range I can feed. I have not been including that in
the models.

I added a base inductor of 100uh(r=3) and got the results you
predicted. The 28 foot radiator is now showing -3.75 dbi gain!
Lesson learned!

The matter of the phase angle and the feed point voltage is currently
over my head, I will study it further.

I am using the TLW program from the Antenna Handbook to determine an
appropriate match. I have not tried to verify those calculations with
a lab project YET!

Once again, thank you for the assistance. I was getting pretty
frustrated...

The helix feature is found under the Wires window under the create
menu. But it is somewhat complicated. A lumped inductance load
will get you started.

The problem with feeding an impedance of 1.2-j1400 ohms is
getting power into the antenna without dissipating most of it
in the matching network.

Hi John,

Well, this still does not tell us how you got here, only that when you
did you immediately stumbled.

Could it be that you inverted the results too? You know, it would
make more sense as an explanation than anything else.

Besides, if you skip the losses, the two will have such similar gain
figures that no one would be surprised by the razor thin margin of
difference.

Let's review this response for its pity quotient:

Asked: At one length, one coil exhibits
Vf = 0.02,
reduce the coil length, what length for the SAME coil would that be
to render
Vf = 0.2
for instance?

1. We are not changing frequency;
2. we are not changing diameter/lambda
(nor in fact changing diameter OR lambda);
3. we are not changing pitch/lambda
(nor in fact changing pitch OR lambda).

Answer? Change the coil, change the Vf, and the turns/lamda.

********** W R O N G ! **********

Draw another pity card and do not pass go.

Source record: 60758

If there's no conductor loss in a model, and no ground loss from a ground system (which can be simulated with a MININEC type ground), the gain of an infinitesimally short vertical should be about 0.45 dB less than for a quarter wave vertical. The gains for intermediate lengths should fall between. The gain difference is caused by the change in current distribution as the antenna length changes, which in turn causes a slight change in the pattern shape.

If you're seeing a report of higher gain from the shorter antenna, something's wrong. Do an Average Gain test to make sure there are no numerical problems, and also check the segmentation to make sure it's reasonable. And, of course, make sure that the length is the only difference between the models.

You'll find it in the EZNEC manual index under "Helix Creation".
(There's lots of other good information in the manual, too.)

> I believe I can get the same results by inserting an appropriate load.
> It will just be a little more cumbersome.

It'll be less cumbersome, but you probably won't get the same results.
The amount difference will depend on the geometry of the helix. However,
a lumped load is adequate to illustrate the phenomena you're investigating.

> Lesson learned!

The loss is due solely to the inductor's resistance -- you'll get the
same result by replacing the inductor with a 3 ohm resistor. The amount
of gain reduction due to the inductor will get worse and worse as the
antenna gets shorter and shorter, for two reasons. The first is that the
antenna's radiation resistance drops as it gets shorter, so the inductor
loss becomes a greater fraction of the total feedpoint resistance. The
second is that you need a larger inductor for a shorter antenna and,
assuming a constant Q, that means more inductor resistance.

>for instance?

Well, let's help Cecil navigate this with his MENSA walker.

First, myopic translations of SAME coil are bound to confuse him into thinking that this means the coil was never shortened. We'll put a bullet into that suffering idea right now - the coil is shorter.

Investigating Fig. 1 reveals there is no way to resolve the Vf through shortening a coil. Only Cecil could argue there's a pony in all that horseshit, so while he's saddling himself to that mound, let's proceed to see why his dotaged enthusiasm is ill-founded.

Fig. 1 is based upon the formula (32). Nowhere in that formula is there a turns. Turns may be found, but the specification, s, is for pitch. Pitch for any coil remains the same irrespective of its length. Frequency does not change, diameter does not change; it then follows that Vf does not change when a coil is shortened.

So, the short answer that eludes Cecil is that the question above (or its variants) has no other answer than the one value already provided. By reductio ad absurdum, any kink in a wire that describes an arc of a helix with a large D for a small s; and Cecil would impose his curious theory's delay based on his poor reading skills on Corumï¿½.

Turning aside what is obvious (that having been answered separately);
we can observe that one coil of a fixed pitch (it seems to bear
repeating for Cecil) does not exhibit a Vf increase from 0.02 to 0.2
by cutting the coil down to one turn. Cecil needs to accomplish what
is doable instead of turning to radical solutions that fail early.

This is really strange. You are agreeing with what I have been saying
so your argument is with Gene, not me.

What I have said is that as the pitch is decreased the VF increases
and vice versa.

> wrong?

Assuming that your vertical is ground-mounted, getting the "right answer" for this question depends on the quality of your wire models, and especially your assumptions about the ground plane, and the way your vertical connects to it.

A classic 1/4-wave vertical monopole working against a very good radial ground system such as used in AM broadcast should produce a peak gain of around 5 dBi. The theoretical max for such a system with perfect conditions is 5.15 dBi.

Electrically short(er), base-insulated vertical monopoles, for a given frequency, have lower radiation resistance at the feedpoint near the tower base. So, given the same r-f resistance in the path to the ground plane, the radiation efficiency of the shorter system will drop.

RF

so why would a company like m2 go with linear loading over the much simpler to build coil? and how in the world do you measure the Q of the loading section when it is a large percentage of the size of the element? Does Q even really mean anything in a system that is radiating? Since some of the energy is being radiated along the length of the loading segment i would expect it to look very lossy compared to a small coil.

You can't change the Vf by shortening a Vf = 0.02 coil, hmmm?
Remarkable shortening of your own theory there.

Perhaps you might want to try again using real numbers. Simply
because you play the pity card of forgetfulness (blaming your reader
usually as a bluff) we will reprise the question once again:

Asked: At one length, one coil exhibits
Vf = 0.02,
reduce the coil length, what length for the SAME coil would that be
to render
Vf = 0.2
for instance?

1. We are not changing frequency;
2. we are not changing diameter/lambda
(nor in fact changing diameter OR lambda);
3. we are not changing pitch/lambda
(nor in fact changing pitch OR lambda).

SAME coil means the one being offered, and being shortened - all other
provisos stand

lying as normal "dr" death I see

but to answer your question the concention with rec.radio.cb is that
the origainl poster posits that ARRL is responible for the near
constand of Homosexaul bashing in Radio Newsgruops such CB and to
another poster in the read Shortwave for that matter.

that the explanation is Bull not with standing is a on topic thread to
extent it sparks a discussion of why do so many people in the Radio
NG's choose to make homosexauly based attacks

as to the real reason why the radios NG has gotten into the gay bash
state they have is someothing of mystery to me, since the ARRL
obviously lacks such power

1287. Skirt Chaser is right the ARRL is responsible for all the homosexual posts.

So Dave, have you built a NEC model of the antenna? Do you know that the loading stub really has unequal currents on its two legs? Since that current is fairly close to the element itself, is the net current (the antenna current) on the stub in phase with or out of phase with the element current? What about the efficiency reported by NEC--if you use zero loss conductors versus the loss of the actual aluminum used in the antenna?

>From your description and the picture I found on the m2 website, it seems to me they are using the stub to make the antenna more mechanically robust than they could with no support. Whether it causes poor performance over what could be done with loading coils at the same positions as the stubs attach or not, I don't know, but a NEC simulation should shine some light on that question. You could start with a simple loaded dipole simulation, though that wouldn't tell the whole story.

I do know that it's unfair to completely discount all stubs because people misuse them. Even if people regularly misuse them, it's no reason to discount them: it's reason to learn when they are appropriate and avoid misusing them. Though I don't know about the performance of your particular antenna, I do know that stubs can be very useful in providing reactances and resonators in a variety of applications, and I do know how to analyze situations in which I use them.

Cheers,
Tom

One of the many very handy things about superposition is that it allows us to separate the radiating and transmission line properties of a linear loading section, analyze them separately, and add the results(*). So the Q of the linear loading section can be determined from its transmission line properties without radiation being involved. This can then be directly compared to the Q of a non-radiating inductor. As Tom W8JI has pointed out, the comparison is often not very favorable to the linear loaded antenna.

You'd have to ask M2 why they do what they do. I suspect it's because a lot of amateurs don't understand the loss mechanisms involved, so are under the mistaken impression that linear loading is less lossy than a good inductor. And very few amateurs are capable of making even crudely accurate gain measurements or even comparisons so the vast majority would never know which is better. Smart companies give the customers what they want.

(*) This is done by separating the currents on the two conductors into two sets of currents, common mode -- which radiate -- and differential, which don't.

reducing cost is a big part of business also, why produce a more complex and more expensive antenna if you could sell the same performance with a simpler design? after all, hams are generally cheap.

>
>>and how in the world do you measure the Q of the loading
>>section when it is a large percentage of the size of the element?
>
> Why would that be difficult?

where do you connect your probes? and what are you actually measuring? since some of the energy is being radiated in between any two points where you could connect probes or measure currents the thing you are measuring would exhibit a more resistive (read VERY lossy) characteristic than a small coil you would put in the 3" gap that the linear loading segment spans where it connects to the middle of the element. and since the linear loading rods are not that far from the element itself they will couple strongly to the inner part of the element.

>
>>Does Q
>>even really mean anything in a system that is radiating?
>
> It does if you want to use it in a trap.

its not a 'trap' its a loading section, meant to make a slightly shorter than 1/2 wave element resonant. high Q for a trap makes sense, not for a loading section like this. i think if you base the efficacy of the loading capability on some notion of Q it will likely be misleading. a better measure would likely be a field strength comparison.

>
>>Since some of the
>>energy is being radiated along the length of the loading segment i would

> . . .

Unfortunately, "perfect conditions" includes a perfectly conducting ground far beyond the radial field, a luxury neither we nor the broadcasters have. The maximum far field (sky wave) gain of a ground mounted quarter wave vertical over average ground, with a completely lossless ground system, is on the order of 0 dBi, and this occurs at roughly 25 degrees above the horizon (both depending on frequency as well as ground characteristics). See the EZNEC example file Vert1.ez as an illustration. Its MININEC type ground simulates a lossless ground system.

You can't change the Vf by shortening a Vf = 0.02 coil, hmmm?
Remarkable shortening of your own theory there.

Perhaps you might want to try again using real numbers. Simply
because you play the pity card of forgetfulness (blaming your reader
usually as a bluff) we will reprise the question once again:

Asked: At one length, one coil exhibits
Vf = 0.02,
reduce the coil length, what length for the SAME coil would that be
to render
Vf = 0.2
for instance?

1. We are not changing frequency;
2. we are not changing diameter/lambda
(nor in fact changing diameter OR lambda);
3. we are not changing pitch/lambda
(nor in fact changing pitch OR lambda).

SAME coil means the one being offered, and being shortened - all other
provisos stand

The antenna gain of a half-wave dipole relative to an isotrope is
1.61.

What are the gains relative to an isotrope of -

A dipole with one reflector.
A dipole with one reflector and one director.
An N-element dipole array like a Yagi.

Only approximate answers are needed.

Thanking you in anticipation.

Reg.

You are confusing a direct correlation between cost and price.
Marketing and demand that rises from marketing determines price, not
cost. Hams pay price which is in excess of cost. This is proven
everyday when they pay for a pre-fab dipole made of two pieces of wire
and three insulators. You don't think they are paying cost for that
alone do you? If so, they would buy two pieces of wire and three
insulators instead.

The profit motive does not have to make sense.

>>>and how in the world do you measure the Q of the loading
>>>section when it is a large percentage of the size of the element?
>>
>> Why would that be difficult?
>
>where do you connect your probes?

At the source where loss counts. There is no way you are going to
measure unloaded Q if that is your goal - it doesn't matter that much
anyway unless it is for a trap.

I haven't come across any distributed load traps unless someone wants
to stretch meaning to include resonant lines. Even then, the same
answer applies.

>and what are you actually measuring?

Q, what else?

>since some of the energy is being radiated in between any two points where
>you could connect probes or measure currents the thing you are measuring

Ummm, is this a problem? If you want to measure Q and put it in a
bottle, perhaps it is.

>>>Does Q
>>>even really mean anything in a system that is radiating?

Aside from the difficult language, you are not going to find a
scintilla's worth of difference in what you propose to do with an FSM.
It serves the purpose, easily.

As for Q, you need to distinguish between loaded and unloaded Q. Next,
you need to put a metric on what you mean by "high" Q. This is
because you are probably not going to measure anything higher than 8
to 12 for a "slightly shorter than 1/2 wave" antenna. I would find it
remarkable if the unloaded Q of any load would give you something as
bad as a Q in the 20s or 30s.

>and using relatively large diameter aluminum rod likely has less loss than a
>wound coil.

To say the least, but again, anyone can conspire to fail
magnificently.

>You appear to have forgotten which side you were arguing
>but 1/2 of a turn should increase the VF over one turn.

You can't change the Vf by shortening a Vf = 0.02 coil, hmmm?
Remarkable shortening of your own theory there.

Perhaps you might want to try again using real numbers. Simply
because you play the pity card of forgetfulness (blaming your reader
usually as a bluff) we will reprise the question once again:

Asked: At one length, one coil exhibits
Vf = 0.02,
reduce the coil length, what length for the SAME coil would that be
to render
Vf = 0.2
for instance?

1. We are not changing frequency;
2. we are not changing diameter/lambda
(nor in fact changing diameter OR lambda);
3. we are not changing pitch/lambda
(nor in fact changing pitch OR lambda).

SAME coil means the one being offered, and being shortened - all other
provisos stand

Dave wrote:
> so why would a company like m2 go with linear loading over the much simpler
> to build coil?

Marketing, marketing, and marketing.

Manufacturers have done an excellent job making everyone think traps are lossy and coils are bad. Some companies sell things significantly worse than what they say is "bad".

One company uses a length of small coaxial line to provide a reactance loading their antenna to 80 meters, even though a piece of doorbell wire on a toilet paper tube would have less series resistance for the same reactance.

Another one markets an antenna they say uses "resonators" instead of "lossy traps", but when you analyze the resonator it is actually just a self-resonant coil used as a trap, and that makes ESR terrible compared to some of the poorest L/C traps we could build.

Linear loading is just another ploy. It lets them say "no lossy coils" when in effect what you have done is stretch a coil into an elongated single turn. When you do that you lose the advantage of mutual coupling aiding in reactance, so you have to increase conductor length to get the same reactance. A longer current path means more resistance. Worse yet, the stub places strong electric fields between two conductors (increases capaciatnce shunting the inductance), and that increases circulating currents that do nothing but heat the stub while decreasing bandwidth.

Linear loading is exactly like doing everything we don't want to do to an inductor...but with one exception. The sole exception is a slight imbalance in currents allows the stub to radiate a little bit, and that radiation has the overall effect of allowing the linear loading to move the effective position of the load insertion to a DIFFERENT location than the place where the element is insulated.

Say we have a 50 foot long element insulated 12.5 feet from the boom on each side. If we added linear loading with the stub extended OUTWARDS from that insulator it would look like we really inserted the loading a bit further out on the element than the point where the element is actually broken with an insulator. That can be an advantage because EFFECTIVE current distribution, the vector sum of current that actually causes radiation from the stub and element combination, would be more uniform over distance. We would effectively have more ampere-feet, and slightly higher radiation resistance.

On the other hand it is just as easy, when we don't understand how the antenna works, to screw up and fold the loading stub inwards from the element insulator and move the effective point where the loading is added closer to the boom.

That's why I say it is a soup of things going on, and the results can be not as bad as other cases. The general rule is, however, anything we can do with a linear loading system we can do better with a coil. Sometimes a little better, sometimes a lot better.

>and how in the world do you measure the Q of the loading
> section when it is a large percentage of the size of the element?

Substitution and measurement of changes in feedpoint and radiation charcteristics, formulas to cross check, and dorect measurements of how the stub itself behaves when balanced.

>Does Q
> even really mean anything in a system that is radiating?

That's why I defined Q as reactance over ESR, and not the less useful measurement of bandwidth. When the series resistance increases for a given reactance, you might as well use the loading system with less series resistance for the same reactance. That would be an inductor of proper form factor.

> Since some of the
> energy is being radiated along the length of the loading segment i would
> expect it to look very lossy compared to a small coil.

....but that radiation does nothing useful, except modify the effective location where the equivalent lumped load is placed. It doesn't magically give you something that would otherwise turn to nothing.

I think the picture in your mind is remotely like the seriously flawed but somewhat popular idea that a folded element has increased efficiency from increased radiation resistance. 100 feet of wire in a 50 foot linear spatial area is still just a 50 foot antenna. All you can do is shuffle the effective current distribution around a bit, you can't make it behave like it is longer than 50 feet, and a coil will do the same thing for shuffling current as a linear loading system.

All of this aside, the only thing that matters is how happy the antenna makes people. Doesn't matter that my dipole beats a linear loaded two element 80 meter Yagi. The yagi impresses people more. My own personal choice is to use a dipole on the air, but to show people visiting that I have a 2 element (linear loaded) Yagi.

What are their dimensions?

Size 2643012702 (.38" O.D., .25" I.D., .25"L) has a Z of about 12 ohms at 7 MHz, 15 ohms at 10 MHz.

Size 2643625103 (.625" O.D., .312" I.D., 1.125"L) has a Z of about 80 ohms at 7 MHz, 100 ohms at 10 MHz.

Dave,

it boils down to the "problem" we were rehashing here - distribution of current along the antenna element. I tried to highlight that, but it gets lost in the "contributions" of the "same current worshippers".
If you would model loaded element with 1. lumped inductance, 2. real solenoid and 3. loading stub - wires folded back onto element, you would see the variations of current distribution along the element and its effect on the design or optimization of multielement Yagi (cancellation in overlaps).

The reason why antenna manufacturers used loading stubs to shorten the elements, was the idea that it would be less loss (it's "just" a wire) and would be more efficient than "some" lossy coil. You hardly find commercial loaded Yagi with coils as a loading element. They all used "nice, efficient" loading wires until W6 - I forgot the call, wasn't happy with performance of his 80m KLM loaded Yagi, replaced the "efficient" loading stubs with good quality coils and found that antenna performed much better. Better gain, better pattern, F/B (Richard can search for that "no good" article in CQ Mag. and query them). Few other hams did it too later and found the same.

This is another proof of difference in performance when considering the proper loading and proper treatment of load in the standing wave (antenna) environment.
The effect gets magnified in multielement arrays and has significant impact on the pattern and F/B. This is why we are arguing about proper treatment of the current distribution along the loaded element. How can it be the same in a coil, when it is demonstratively different in the loading stub (EZNEC shows THAT). When you have "wire" folded on itself three times and affecting currents (cancellation) along them - it gets worse than just current drop along the loading coil. The unbelievers would try to tell you that there can't be drop of current along the coil, much less along the loading stubs (it's just a piece of wire), but if you consider standing wave environment along the antenna element, then it all becomes clear and explains the behavior of various loading elements, current distribution in them and effect on the element and array. So replacing loading stubs with good quality coils WILL improve the performance of loaded Yagi, gain and especially give you better pattern and F/B. The same goes for Beta match at the center of element as used by i.e. Hy-Gain 402BA, replace it with few turns of copper tubing to get 50 ohm match to the coax. Now there is good

fiberglass tubing available that can be used for strong insulators and forms for the loading coils.

Standby for W8JI mumbo-jumbo, bla, bla, bla.... he has to be the last standing "trutz" man! You can verify and decide.

That's right, for me it was enough to remember the results. If you want more info, you can Google it or SeeeKeeew it. You ain't paying me and for free advice this should do it.

If I wanted to get details and build the coils, I would dig for it. For now I have better idea for loaded loop antenna, so it is on the back burner. Now you are mixing Washington in addition to Fractals - not very good picture of your "fakultys" if you have to rely on social security. Any constructive ideas besides filibusters and "Bush- baaad"?

Sayonara!

73 (doesn't need 's - they are included) - if I was nitpicker like you :-)

I disagree about the penetration depth. The depth depnds on frequency and soil characteristics, but at 160 m the "skin depth" (the point where the potential has fallen to 1/e of its original value) would normally fall in the range of 10 - 30 feet.

If you live over a silver mine or the Sahara desert, your mileage will vary.

Seems Richard Clark has proven that it doesn't change between
the "known" limits of 1.0 and <0.02. Where did those "known"
limits come from anyway?

For a single turn coil, seems the VF would roughly be the pitch
divided by the circumference, something that would equal 1.0 only
when the pitch and circumference were equal.

For the 4 TPI, 6" diameter coil, the VF formula yields 0.02.

The pitch divided by the circumference yields 0.013.

In a yagi gain is not related to the number of elements (as long as there are enough) once the boom gets significantly long. The point at which it is significantly long could be argued to be somewhere between 1/4 of a wavelength to a wavelength, where the effect is hard to see at 1/4, and absolutely there at 1.

Are you looking for some way to reasonably predict yagi gain? If so, there are a couple 3 equations which do a very fair job. Basically you need one for short yagis, and another for long. If you're interested, I'll dig the short boom out for you, but I can't right now, as I'm already waaaay behind schedule for getting to work.

Here's the one that works best for long booms -

G = 10 log (5.4075 B + 4.25) for B GT 1

Where G is gain in dBd and B is boomlength in wavelengths.

Cecil,

Since you have fallen back to the old "round and round the helix" model there is little hope for agreement. It is interesting, however, that even the Corum model for Vf at resonance is not as slow as the purely geometric model. Must be those standing waves again.

73,
Gene

> frequency as well as ground characteristics).

The above is an understandable conclusion using NEC analysis, however it is not supported empirically. If it was, AM broadcast stations would perform very much differently than they do.

The measured data in Brown, Lewis & Epstein's 1937 benchmark paper "Ground Systems as a Factor in Antenna Efficiency" proved that the *radiated* groundwave field from a vertical monopole working against 113 buried radials each 0.41 lambda in length was within a few percent of its calculated peak value for a radiation pattern with maximum gain in the horizontal plane. The path length for the measurement was 0.3 miles, which was in the far field of the vertical monopole configurations measured.

BL&E's measurements, and the results of thousands of measurements made of the groundwave fields of MW broadcast stations using such radial ground systems ever since demonstrate that their peak gain always lies in the horizontal plane.

It is true that, as a groundwave propagation path becomes longer, the field measured at increasing elevations above the earth at distant ranges might be higher than measured at ground level at those ranges. But that is not because more field was launched by the original radiator toward those higher elevations -- it is because the the groundwave path has higher losses, which accumulate as that path lengthens. Therefore a NEC plot showing the conditions reported in the quote above do not accurately depict the elevation pattern as it is launched from the radiator, and the groundwave field it will generate.

There are software programs designed for calculating MW groundwave field strength given the FCC "efficiency" of the radiator and the conductivity of the path. The radiator efficiency is the groundwave field developed by the radiator with a given applied power at a given distance (1 kW @ 1 km). These values must meet a certain minimum level for the class of station. I think in all cases, they must be within ~0.5 dB of the theoretical value for a radiation pattern with its peak gain in the horizontal plane. In the case of directional MW antennas, this performance must be proven by field measurements.

Finally, standard equations show a peak field of ~137.6 mV/m at 1 mile from a 1/2-wave dipole radiating 1 kW in free space. The calculated groundwave field at 1 mile radiated by 1 kW from a 1/4-wave vertical MW monopole over a perfect ground plane is ~195 mV/m. This is the same field as generated by the free space 1/2-wave dipole, when all radiation is confined to one hemisphere (137.6 x 1.414).

The groundwave fields measured from thousands of installed MW broadcast antenna systems confirm that their intrinsic radiation patterns are within a fraction of a decibel of that perfect radiator over a perfect ground plane, no matter what is the conductivity at the antenna site (N.B. Reg).

Thanks Tom,

If we have 5 or 6 elements spaced approx 1/4-wave apart, that makes a boom length of 1 wavelength and a gain of 10 dB relative to a dipole.

Can experienced users of Yagi design programs confirm that 10 dB is in the right ballpark?

Yes please, I would like to see the equation for short booms and fewer elements on your return from the salt mine.

So you cleverly avoid the problem of how to calculate the effects of ground conductivity by laying down more than enough radials of more than sufficient length to hide the effects.

B,L & E sure had the right idea.

But hardly a satisfactory economic engineering solution.

Anyone who says the current goes "round and round the helix"
is wrong. Anyone who says the current goes like a "short circuit
through the coil is wrong."

There is NO rail "round and round the helix'! There is NO rail
"short circuit through the coil"! There is, as usual, something in
between the two rails. Looking at Fig. 1 in Dr. Corum's IEEE paper:

For a diameter/wavelength ratio of 10^-3

If the coil is1000 turns/wavelength, the VF is 0.8 which is closer
to a "short circuit through the coil" than it is to "round and round
the helix".

If the coil is 5000 turns/wavelength, the VF is 0.18 which is
closer to "round and round the helix" than it is to a "short
circuit through the coil".

The field coupling between the coils is responsible for the VF
not being as slow as the purely geometric model but there is
a practical physical limit to the number of coils that are being
coupled.

Coils are a combination of primary and secondary characteristics.
All the primary characteristics need to be taken into account. Some
of the secondary characteristics can be omitted under certain
conditions.

I have used several approaches. In raised houses, I have used the
floor as an entrance for the feed lines. In my current location with
a slab-floor, I feed the leads behind the vinyl siding and enter the
home though a wall outlet with two SO-239 feed-thru connectors in the
plate. The wires go into a CATV cover that happened to be on the
house already, where it is grounded to the ground-rod used for CATV
and the electrical panel. From there, my coax is run along the ground
at the edge of the house to a point at which I plan to setup a
vertical antenna during those times I wish to use it. When not using
it, I will remove it and place it back in the garage. (we have
neighborhood covenants :( ).

In a previous home, I drilled a hole in the bottom of a closet corner
(inside near the wall so it won't be seen by someone casually looking
into the closet) and run my cables under the closet door to my rig
which was on a table next to the door. A 3 inch piece of PVC pipe
stuffed with plastic and foam sealed the weather and bugs out. When I
left, a wood disk was glued and nailed into place so the hole was not
obvious or offensive to the landlord when I left.

I am currently working on a different kind of 'flagpole' hidden
antenna idea for this location so I can temporarily install dipole
antenna(s) as desired without upsetting the neighbors.

I hope this helps.

John,

Thanks for the info.

What I've got are the .38 OD .25 ID ones. Thanks for the info. Seems like I've been overkilling the VHF stuff. I think my 2m beam has 50 of them on it, and if they're 12 ohms down at 7MHz...

I'll save that fair-rite link for future reference, but right now it's locking my browser!

I guess the bead balun would be more broadbanded. I've not yet measured the self-resonant frequency of my toroidal choke, but I'd imagine it's somewhere in mid-high HF.

I think I'll string up a hundred beads and use that as my choke.

Thanks for the input es 73,

Dan

I stand corrected!

I should have calculated it.

Sorry for including gross misinformation about MF & HF skin depth in typical soil.

A modest radial system will whip a deep ground rod, though. I'm about 10% tempted to break out J.D. Jackson' Classical Electrodynamics and try to calculate the RF resistance vs. depth of a ground rod, but I know it's going to be hard to deadly.

Quantitative is always best in this sort of discussion, for sure.

Thanks for the response.

Might have been when I was out of town. Except for a
single toroidal coil anomaly, all of the measurements
show a different magnitude of current at the two ends
of the coils. Most of my measurements have been at
the self-resonant frequency of a loading coil.

A 75m mobile bugcatcher coil is part of a standing wave
antenna with near-equal forward and reflected currents
flowing in opposite directions (phasors rotating in
opposite directions). As a result, the standing wave
current on the antenna has essentially the same phase
as the source current all up and down the antenna
whether a loading coil exists or not. Standing wave
current on a mobile antenna cannot be used to measure
phase shift or delay through a wire or a coil.

That standing wave current is of the form,
I = Io*cos(kx)*cos(wt), and cannot be used to determine
phase shift. So the major measurement mistakes were
not in the magnitudes, which are relatively easy to measure,
but in the phase-delay measurements, which were invalid.

The major conceptual mistake concerns standing waves,
not coils. It appears that some people didn't even realize
that they were dealing with a standing wave current on a
standing wave antenna.

The best estimates of actual delays through the coils seems
to come from the Dr. Corum IEEE paper where formulas
are given for the VF and Z0 of a coil. For the particular
coil being modeled in EZNEC, the VF formula yields
~0.02, or about 37 degrees for a 6" long coil on 4 MHz.

So you think it is preferable to install a less than optimal radial ground system, as long as you can calculate how deficient it is?

MW broadcast stations want/need maximum groundwave coverage. Installing a "BL&E" radial ground system will provide that for all conductivity conditions at the tx antenna site -- which equates to a very satisfactory and economic engineering solution for this application.

You can't change the Vf by shortening a Vf = 0.02 coil, hmmm?
Remarkable shortening of your own theory there.

Perhaps you might want to try again using real numbers. Simply
because you play the pity card of forgetfulness (blaming your reader
usually as a bluff) we will reprise the question once again:

Asked: At one length, one coil exhibits
Vf = 0.02,
reduce the coil length, what length for the SAME coil would that be
to render
Vf = 0.2
for instance?

1. We are not changing frequency;
2. we are not changing diameter/lambda
(nor in fact changing diameter OR lambda);
3. we are not changing pitch/lambda
(nor in fact changing pitch OR lambda).

SAME coil means the one being offered, and being shortened - all other
provisos stand

Hi Mike,

Well, you have a serious problem embodied in your statement. Neither Cecil nor Yuri made any measurements. Perhaps Yuri observed some shrink tube that had charred while he was working power, but actually that is a stretch (not shrink) as he "observed" this only after the fact. You certainly have read enough correspondence to observe for yourself that Yuri cannot describe any system fully, so saying there were correlations can only come from a heated imagination (more current in than coming out). If there have been any experimental details made under observed conditions, we have to credit Tom.

My take on it is that Richard just loves yanking a chain that's particularly easy to yank and will invariably respond in a way that allows more yanking.

Everybody has long since agreed in principle; it's just that some people remain buried so deeply in the forest that they can't see it for all the trees. Or maybe it's that they are buried so deeply in the pile that Richard was mentioning that they can't find the pony that's been there all along to ride out on.

All this wave BS is just mathematical abstraction to 'splain what's really going on anyway. If one is smart enough to actually get through the math without making computational or conceptual errors, he's still going to be lost if he doesn't relate it back to what it is that the math is explaining. His loss; too bad.

Cheers,
Tom

Marc,

That's a fine picture of a variable capacitor, but how are we supposed to know how the connections inside are made, or what the capacitance values are? You may be able to tell if you inspect it carefully from the outside. Even if I have one that _looks_ similar (which I may well have) I would not rely on its having the same connections or capacitance values as yours.

Have you done any analysis of the loop to see what capacitance you need to tune it to the frequencies you care about? Reg Edwards has on his website a program that's useful for analyzing loop antennas. I believe it's only set up for square loops, but if you enter side lengths to give the same loop area as you have, you should get quite close to the same performance. You may find it's helpful to use a larger cross-section wire in the hula-hoop, for lower resistance.

How will you tune the antenna to different frequencies if the capacitor is sealed in the box? Will you provide a hole for adjustment? How will you feed the antenna output to the receiver? What frequency range do you hope to cover?

I fear there are more questions than answers...but questions are good if they get you thinking about the whole situation before you put a lot of work into something that may not do what you expect or what you want.

Cheers,
Tom

You will need a VOM to check, but it appears that numbers 1, 3, 4, 6,
and 7 go to the frame (stator). Screws A, B, C, and D look like
trimmers, not wire attachments (that is, they are small variable caps
in parallel to the main caps).

Numbers 2 and 5 appear to be the main capacitor connections with
reference to the frame. This looks like an old AM tuning component
for which you would have two Caps. One for tuning the front end, the
other for the local oscillator, and the trim caps take care of both
matching the antenna, and keeping the IF tracking between the two
(usually adjusted at the high end of the band). The two main Caps
also have different maximums (because they tune over different ranges
of frequencies).

None of this is of any consequence to you for your project, however.
You need only confirm my guess of the frame connections. If that
bears out, tie them all together, or use just one and ignore the rest.
This is one half of your project's Cap. If 2 and 5 show no continuity
to anything else (except the screw heads, perhaps), then that confirms
their status as being the rotor half of the variable Cap. Tie them
together for the other half of your project Cap.

If there is any variation in testing with the VOM for continuity, you
may have a split frame. Visual inspection should reveal two
assemblies that would be very similar in construction. Take hints
from discussion above to reduce the complexity of all the leads.

I am not sure how to connect the wires to the loop, but they go to the tabs
that are numbered.
The screws go to 4 small trimmer capacitors for adjustments. Usually that
kind of capacitor comes out of an AM/FM radio and the capacitors are for
fine adjustments of the ranges. One for the frequency of the oscillator and
one for the tuning for each band. They mostly affect the high end of the
band as they are small in compairison to the main capacitor. The are hooked
internally to the main capacitors the shaft adjusts.
If you look close you will see the half round plate turn as you turn the
screw. A coil is usually adjust for the low end of the band. You go back
and forth from the low end , adjusting the coil and to the high end
adjusting the screw for the best tracking across the band. The oscillator
for the frequency readout and the tuning for maximum signal.

Hi Tom,

The "secret," as you put it, is still as hidden to them as the WMD.

As you infer, it is rather all too easy to stir, but harder to
accomplish. Inferior talents prove that daily. None here see but
perhaps a tenth or less of what I've written; because as with good
technical writing, the best comedy is what is left after pruning the
excess from it.

Actually, it's just the other way around. How is one ever
going to understand what's really going on by superposing
waves to the point where half the information is lost?

And how does one know the failure point of the lumped
circuit model if they don't understand the superior
distributed network superset model?

The impedance of type 43 beads keeps climbing (though not in
proportion to frequency) to well above 100MHz.

They're the 1/4" long ones.

I dunno, I like 1200 ohms... 24 times my feedpoint impedance?

I'm sure it's overkill given the induced currents that will flow
anyway...

I've got the beads, though, and I could use it on 80m too...

I can only basically have one antenna up at a time so I've gone over to
modular antenna parts and so one lower-HF bead balun can be used on
whatever I'm playing with at the time. I've only got one permanently
installed antenna, and that only until the wind blows...

Ah, apartment life.

Make that: "If we have 5 or 6 elements optimally spaced along a boom length of 1 wavelength, we can hope for something in the region of"

>a gain of 10 dB relative to a dipole.
>
>Can experienced users of Yagi design programs confirm that 10 dB is in
>the right ballpark?

That's about the best gain we can hope for, given a one-wavelength boom to play with. On the other hand, poor choices of element lengths and positioning will produce many dBs less forward gain... or even gain in the opposite direction.

>
>Yes please, I would like to see the equation for short booms and fewer
>elements on your return from the salt mine.

There isn't really "an" equation for gain versus boom length, because boom length is only an indicator of the potentially achievable gain. But nothing "makes" a yagi deliver any particular gain figure.

Quite the opposite: very often, yagi designers will deliberately sacrifice some forward gain to obtain better performance in other important respects. These can include a cleaner pattern, a more convenient feed impedance and better tolerance to element loading by rain and ice; and all maintained over a wider bandwidth.

Yagis that have been single-mindedly optimized for maximum gain tend to be poor performers in other respects - especially tolerance to element loading.

The equation that Tom quoted is just the best-fit line through the gain figures for one particular family of reasonably good long yagi designs. Other good designs will have similar gain, but different performance in other respects. And for every good yagi design, there are many more that come nowhere near this level of performance.

Reg,
I have run EZnec on a KLM 50-7LD. This is a 7 element on a 20 foot boom.
Almost exacty 1 wavelength long. There is a dual driven element; so, it is
more like a 6 element beam. The gain in free space computes to 11.01 dbi.

Ian is correct, and I should have stated that this equation is for well designed yagis. Also there were 3 families of antennas involved, plus some odds and ends. The K1FO models all are within about 2 tenths of a dB of the line in question.

Also, if we move to pure gain number, as in the multiplication factor, the line produced by well designed yagis is virtually ruler straight above 1 wavelength, and up to a a point I can't remember. It's above 10. And then it starts to roll off, which makes sense. I'd have to go look at the models again to find where the rolloff becomes noticable.

The capacitor will go across the coil or in other words connect to the ends of the coil.

The capacitor is made of two opposing conducting plates with an insulator between them. For most tunable capacitors the insulator is air. One plate will stay in place and the other will rotate by turning the shaft. When the plates are meshed together you have maximum capacitance and lowest frequency of operation. You will have to look through the case to find the connections to the opposing plates for each section.

I can't tell from the picture but it looks like this box has two or more sections. You can parallel the sections together if one section does not have enough capacitance.

Also hard to tell is what the "screws" are in the picture but I expect
that they are trimmers (additional small adjustable capacitors) that are
arrayed across the main capacitor sections for alignment purposes.

I raise the bottom sash of the window and install a metal plate across the opening.
The sash must be sealed to both the plate and to the upper sash to prevent leaks. The plate itself is connected to the main shack ground just outside. Bulkhead style connectors both UHF and N are used for the coax leads. I used an octal socket for the rotor cable and an F connector for a power lead to a mast mounted 432 preamp. The point is that all the connections can be easily removed if there is lightning in the area. I did the same things some years back for my Dad's house in Florida; unfortunately this was after having some lightning damage.

In his previous house with cinder block walls, we put a piece of pipe right through the wall with a downward facing elbow outside. Leave a drain loop on the coax and seal the pipe with insulation to keep out the bugs.
John

Here's what one of the experts told me about superposition.

I agree, however in my current situation I really can't keep going up and down to the roof because I'm renting a suite in the basement and I'm already pushing things with all the feedlines and isopole VHF antennas already up there. The landlord is a really decent guy and has been totally reasonable --- so far. If I keep wanting to do more and more he's going to feel obligated to say no sooner or later.

There's another issue, though, a more important one --- I moved the feedpoint to the SW corner of the roof (pic at http://members.shaw.ca/cyberhun/ham.htm) and used coax for the feedline. But when I was up there, I was so freaked out by the height that I forgot to waterproof the termination --- but I'm not going back up there til I can figure a way to do it more securely. It doesn't matter how many guys are holding the bottom of the ladder. If it starts to slide one way or the other, there's too much leverage for anyone to stop it. Water damage be damned, a fall from that height could be deadly.

Take two PSK signals, superpose them through the same coax,
and see how much information is lost.

This one by Bill Myers, K1GQ, is supposed to work well for short yagis.
I have no experience with it. All of mine is with V/U HF yagis.

G = 3Ln(B) + 9.85

Hi

Its a detonation cord to fragment the canopy in case of ejections..

Regards
